INDEX TO VOL. LXIX

OF

"THE INDIAN MEDICAL GAZETTE"

For the year 1934

[Original Article 'O.A.'; Mirror of Hospital Practice 'H.P.'; Editorial 'E.'; Special Article 'S.A.'; Medical News 'M.N.'; Current Topics 'C.T.'; Correspondence 'C.'; *Italics* signify Reviews; Reviews are placed under the name of the author; they also appear under the heading 'Reviews', where they are arranged according to subjects.]

	Page		Page		Page
A		All-India Ophthalmological Society, Report of the Third Conference of the (M. N.) ..	217	Anklesaria, M. D. Cilia in the Anterior Chamber and Traumatic Cyst in the Iris ..	259
Abdul Wahed, A. K. M. <i>see</i> Chopra, R. N. Toxic Effects Produced by Combined Treatment with Atchirin and Plasmochin ..	213	—————Research Workers' Conference, Eleventh (M. N.) ..	40	Anopheles in Bengal, On the Biological Control of, An Address, delivered at the Fourteenth Annual Meeting of the Central Co-Operative Antimalaria Society, held in Calcutta in February 1934 (Strickland) (M. N.) ..	341
Abscess, Acute Psoas (Srinivasan) (H. P.) ..	447	Allison, A. <i>Forensic Medicine. Catechism Series</i> ..	291	Anthelmintic Treatment with Tetrachlorethylene and Oil of Chenopodium, A Comparative Record of (Manson) (O. A.) ..	500
Achar, S. T., <i>see</i> Cruickshank, M. M. Abdominal Pregnancy Secondary to Tubal Gestation at Term ..	61	Alvarenga Prize of the College of Physicians of Philadelphia (M. N.) ..	160	Anti-Malarial Campaign, The Place of Treatment in an (McQueen) (O. A.) ..	204
Acharyya, R. C. <i>Medical Entomology on Chart</i> ..	292	Amalobiasis, Chronic Intestinal, Treatment of, with Gavano (Chopra, Sen and Sen) (O. A.) ..	130	—————Measure designed to meet a Particular Physiographical Situation in Sylhet District, Assam (Strickland and Gibson) (O. A.) ..	432
Acid and Sanitol Treatment of the Intestinal Fluxes (Palmer) (O. A.) ..	137	—————Intestinal, Carbarsone in (Chopra and Sen) (O. A.) ..	375	—————Work on a group of Tea Estates in South Sylhet (Murphy) (O. A.) ..	437
Acriflavin in Cerebrospinal Meningitis (Vaidya) (C.) ..	418	Amoebic Dysentery, The Outbreak in Chicago (C. T.) ..	457	Anti-Rabies Treatment, A Fourth Analytical Review of Reports from Pasteur Institutes on the Results of (C. T.) ..	407
Acta Aerophysologica (M. N.) ..	102	—————Liver Affections: Symptoms and Treatment, with a Review of 25 Cases (C. T.) ..	45	Antrum of Highmore, A Case of Sarcoma of the Upper Jaw with Sinusitis of the (Sukhavanam) (H. P.) ..	510
Acton, H. W. and Dey, N. C. A Simple Method of Recovering Typical Cultures of Dermatophytes from Pleomorphic Growths ..	601	Anæmia, Aplastic, A Case of (Mitra) (H. P.) ..	145	Appendicitis, Date Stone causing (Mozumdar) (H. P.) ..	84
—————H. W. and Ghosh, L. M. <i>Tinea Imbricata</i> (Tokelau) in Bengal ..	426	Anæmias, The Modern Treatment of the (C. T.) ..	165	—————Lymphadenitis of the Retroperitoneal Glands Stimulating (Bose) (O. A.) ..	579
Adair, F. L. and <i>other</i> . Edited by— <i>Obstetric Medicine: The Diagnostic and Management of the Commoner Diseases in Relation to Pregnancy</i> ..	591	Anæsthesia in Midwifery: A London Experiment (C. T.) ..	103	Appletan, D. and Co. Published by— <i>The Practitioners' Library of Medicine and Surgery. Volume IV</i> ..	110
Addendum ..	159	—————Sodium Evipan, A Study of 30 Cases (Chellappa) (O. A.) ..	685		
Addison's Disease? A Case of (Sarkar) (O. A.) ..	25	Anæsthetic, The Choice of, in Complicated Obstetrical Cases (C. T.) ..	277		
Agglutination Tests in the Diagnosis of Enteric Infections, Present Position of (C. T.) ..	586	—————A New Intravenous: Evipan Sodium (Fitzgerald) (O. A.) ..	67		
Ahmad, B., Grewal, K. S., and Malik, K. S. Further Observations on the Metabolism of Carotene ..	320	Anæsthetics, Spinal and their Clinical Usefulness, Present Status of Various (C. T.) ..	103		
All-Bengal Compounders' Association (M. N.) ..	273	Andre, Z., <i>see</i> Gaffiero, E. Therapeutic Property of Coconut Oil ..	538		
Allergic Manifestation (Das) (C.) ..	598	Andrews, R. A Translation of 'Midwifery for Nurses' ..	173		
All-India Medical Conference, 1934. The Eleventh (M. N.) ..	640	—————R. and Lack, Victor. <i>Midwifery for Nurses</i> ..	469

Original Article

TREATMENT OF TYPHOID FEVER IN CHILDREN

By E. H. VERE-HODGE, M.D. (Cantab.)

M.R.C.P. (Lond.)

LIEUTENANT-COLONEL, I.M.S.

Civil Surgeon and Superintendent, Medical School
Dacca

TYPHOID FEVER in children exhibits certain important differences from the same disease in adolescents or adults. Before the age of twelve severe hæmorrhage and perforation of the intestine are exceptional; on the other hand cerebral symptoms, meningismus, delirium or coma are prominent features, as also is the tendency to respiratory complications. The writer saw in the course of one week no less than five cases exhibiting some degree of meningismus. A happy feature in the young, however, is a singular capacity for recovery even in the most desperate cases. As an illustration may be quoted the recovery of a girl of 12 years, who had 84 days of fever including a relapse, who was semi-conscious for a month, whose temperature at times rose above 105°F. , and who developed pneumonic patches in both lungs.

Until comparatively recent times the treatment of typhoid centred on the prevention of perforation or hæmorrhage, by methods now considered to be of doubtful value, with the result that it is probable that a considerable proportion of patients succumbed to starvation rather than to the actual rigours of the disease. It is clear that a diet insufficient to stabilize wastage will increase these risks by allowing the bowel wall to become thin from starvation atrophy. The starvation treatment is still more dangerous in children, as it will increase the liability to pneumonia and heart failure. Starvation states are particularly badly borne by the young, as there is less stability in the blood-sugar content, and with its fall tachycardia, heart exhaustion, and acetonaemia will develop.

Briefly then, the first consideration in the treatment of typhoid fever is the maintenance of nutrition. In parenthesis, the writer may be allowed to refer to an important diagnostic sign, hitherto, as far as he is aware, not recorded. This sign is the perceptibly higher temperature of the skin over the abdomen, as compared with other parts of the body; it is especially prominent in children.

The maintenance of nutrition

It is estimated that the caloric requirements to maintain equilibrium are 40 per cent higher than in the normal, to be made up almost exclusively in protein and carbohydrate. The assumption that the carbohydrate content is the

more immediately necessary is based on the striking improvement that may be observed when the deficiency—as evidenced by increased rapidity of the pulse, increased prostration, and acetonaemia—is made up. Actually there are difficulties in the way of administering food in a figure anything approaching the theoretical requirements. Of these, the first and almost universal one is the loss of appetite, often associated with complete indifference to the surroundings. Nausea is sometimes troublesome, and finally the digestion, throughout the alimentary canal, is impaired, with a tendency to distension or the development of diarrhoea. Briefly, the food must be pushed to the limit of tolerance keeping a watch for the development of distension or diarrhoea. In doing this it is advisable to keep a measured account of what the patient takes, preferably in terms of calories.

The choice of food lies between glucose, glucose-D, lactose, and Mellin's food, a pure dextro-maltose. The writer prefers the last-named as less likely to give rise to fermentation and distension, and, during the acute stage, prescribes this food in the proportion of one heaped teaspoonful to two ounces of whey. The protein requirements are met by whey or skimmed milk. Should this not be tolerated peptonized skimmed milk may be tried again, with Mellin's food added cautiously.

There is scope for observation on the value of acidified skimmed milk, so valuable in certain other forms of failure of digestion, but there are practical difficulties in the way; lactic acid milk demands skilled preparation and its effective substitute, Lacidac, is not always available.

Finally, a few drops of Radiostoleum are given daily, as soon as it can be tolerated.

Prevention of dehydration

The second and equally important desideratum is the prevention of dehydration. Dehydration must be regarded as an impending danger in all cases, the child is seldom thirsty, is indifferent to all externals or semi-conscious, and the inadequacy of the fluid ingested often passes unnoticed. In one case under the writer's care, admitted to hospital on the 10th day of the disease, the specific gravity of the blood was found to be 1064, necessitating the administration of intravenous saline. The amount actually taken should be measured and if this falls below the necessary quantity, a rectal saline may be given. Rigid figures are unsatisfactory, but the amount aimed at should be proportionate to the estimated adult requirement of six pints a day. The true proof of sufficiency lies in the maintenance of a free flow of urine and a reasonable degree of moisture of the tongue. There is no objection to iced fluids; on the contrary they are pleasing to the patient and help to keep the temperature within moderate limits.

Control of the temperature

Experience in private houses, where skilled nursing is seldom available and the fever is left to look after itself, has led us to doubt the desirability of undue interference with the temperature. Tepid sponging is soothing when the temperature is in the neighbourhood of 104°F. and should be carried out regularly, but the more drastic application of ice packs should be reserved for those cases approaching hyperpyrexia. The ice cap is often abused and applied to the head continuously for days together, to the discomfort of the patient and with the effect of dulling the central nerve centres. In young children with high fever, it is preferable that the ice cap should be placed near and not actually in contact with the head.

Measures taken to reduce the temperature of the surrounding air are of value; these may consist of placing the patient in an ice cradle, which may easily be rigged up, or allowing a fan to play on blocks of ice.

The prevention and treatment of complications

Distension of the abdomen.—In all cases there is liability to distension, which, in minor degree, may be treated by adjusting the diet. Severe distension, however, constitutes a danger, not only increasing the liability to perforation, but, in children especially, inducing complications in the lungs. In addition to direct interference with the movements of the diaphragm and direct pressure on the lung, the abdomino-pulmonary reflex, peculiarly active in childhood, is set up with spasm of the bronchi, the result of which is broncho-pneumonia and collapse. In such cases active measures must be taken; an asafœtida enema with turpentine stupes may be tried, but it will in all probability be necessary to resort to the injection of pituitrin, minims 1-3 according to age, two hourly, assisted by the passage of a flatus tube. In all cases the carbohydrate content of the diet must be reduced temporarily and, in the more severe, it is wiser to withhold all nourishment except water for twelve hours. The cause is often to be found in the administration of too much carbohydrate in the form of barley water or glucose, or in the indiscriminate use of sodium bicarbonate. Distension also occurs when the carbohydrate content is low, and must be presumed to be toxic in origin, or due to adrenal exhaustion. In such cases the exhibition of pituitrin is especially indicated.

Nervous symptoms.—Though not essentially dangerous, these are a sign of increasing prostration and react unfavourably on the course of the disease in that they render nursing and the maintenance of nutrition more difficult. Meningismus, with stiffness at the back of the neck, head retraction and some rigidity of the limbs, may give rise to the suspicion that the meninges are organically involved. Coma or semi-coma may be persistent, or there may be

low delirium. The first indication in such conditions is stimulation, especially when accompanied by a weakening of the first heart sound. The appropriate stimulants are discussed below under the heading 'heart failure'. In the experience of the writer, colloidal calcium has peculiar virtue when there is affection of the central nervous system, whatever form it may take, but especially in delirium. The dose selected is from 0.5 to 1 c.cm. according to age, injected intramuscularly for six days if necessary. In the presence of coma, the urine should be tested for acetone and, if the result is heavily positive, steps should be taken for its neutralization by the administration of glucose by whichever route may seem the most appropriate. At the same time it may be stated that acetone should not be allowed to accumulate in quantity and will not do so if carbohydrate absorption is maintained.

In spite of all difficulties an adequate supply of food and water must be administered and it may be necessary to resort to nasal feeding.

Respiratory symptoms.—In childhood with the active reflexes between the abdominal and pulmonary organs it is not surprising that bronchitis and broncho-pneumonia present themselves as frequent and formidable complications. The development of such complications is undoubtedly encouraged by the traditional method of nursing typhoid patients flat on the back. Children often show a tendency to roll to one side or the other, and should not be prevented from doing so. When the abdominal condition is acute, particularly when there is distension, they will remain prone and in such circumstances it is desirable that they should be placed in Fowler's position.

Posture, nutrition, and stimulation form the basis of treatment; mild expectorants are of value, but must be exhibited cautiously for fear of causing nausea. The importance of atropine (grs. 1/500 to 1/300 hypodermically to a child of 7) must be stressed. It is particularly indicated where there is any massive consolidation or evidence of collapse and when the expiration is prolonged.

Occasionally the respiration, even where there is no pulmonary lesion, becomes markedly irregular or Cheyne-Stokes in character. This condition is an indication for the exhibition of strychnine. Finally, it must be remembered that rapid deep respiration is a sign of acetonaemia of a severe grade.

Heart failure.—It is necessary to maintain a constant watch for either the gradual diminution of the first sound or an increase in the pulse rate. Such signs are induced by toxæmia, by reduction of the blood sugar or by water starvation. Tincture of ephedra is found to be the best of all stimulants, acting as it does in febrile and toxic states by direct stimulation to

the heart muscle nicely balanced with increased vascular tone. It is well tolerated by children and the dose is proportionate to age, the adult dose being one drachm six hourly. A further important effect of this drug is the abolition of bronchial spasm. Adrenalin is useful in case of collapse, but should not be given over long periods owing to a toxic action on the heart muscle.

The timely administration of intravenous glucose (10 c.cm. of a 25 per cent solution to a child of 8) may be instrumental in changing the whole outlook of the case. The writer has found that repeated injections are apt to raise the blood sugar unduly, so it is preferable after the first injection to follow any subsequent injection by giving its equivalent of insulin.

Diarrhœa.—This is a sign of intolerance to the diet and is especially liable to arise if excessive fat, such as is contained in unskimmed milk, is given. Consequently, the first step is the readjustment of the diet followed by the administration of bismuth carbonate should the condition persist. Alkalies, often given as a routine, may be found responsible.

Constipation.—This also is frequently troublesome, partly owing to the somewhat parietic condition of the bowel and partly owing to the absence of the normal roughage in the diet. Many of our patients have been purged during the early days of the disease before diagnosis was established and, though this is sometimes a subject for lamentation, it is by no means clear that this procedure has done anything but good. At the end of the first week, milder methods are used, such as the glycerine or olive-oil enemata, but in addition liquid paraffin may be given provided that it is administered at least half an hour before food; otherwise it may increase gas formation and distension.

Nausea.—This is not infrequent and is troublesome as it hinders the maintenance of nourishment. An injection of atropine—grains 1/500 upwards, according to age—combined with the application of a dilute mustard plaster (mustard one part, flour four parts) for ten minutes, will give relief.

Pyelonephritis.—The infection of the urinary tract with either pure *B. coli* or *B. coli* combined with *B. typhosus* is so common that it may be considered as an ordinary feature of the disease and that prophylactic treatment at the end of the third week is demanded. The condition may be suspected at any time after the end of the third week, if the temperature chart changes type and becomes irregular with high rises of short duration. An examination of the urine will confirm the suspicion. The administration of alkalies sufficient to keep the urine alkaline should be effective in preventing the development of a bacilluria. For older children who can swallow a capsule, the addition of suflavine, grs. $\frac{1}{4}$ to $\frac{1}{2}$, twice a day is advisable.

Where a capsule is inadmissible and infection has occurred, after a full course of alkalies hexamine is employed, but is, of course, ineffective in anything but an acid medium.

Acidosis.—The danger of acidosis is exaggerated, but, if the diet is not well regulated, acetonaemia will occur. In the otherwise normal child, acetone must reach a high degree of concentration before symptoms of poisoning arise, but, in the child with a deranged nervous system, the minimum concentration is doubtless lower. Further, the accumulation of acetone is a sign of sugar shortage. Whichever factor is the more potent in producing an ingravescence of symptoms, the indication is the same, and any marked acetone reaction in the urine should prompt an increase in the carbohydrate section of the diet. Acetonaemia may arise even in convalescence as in the case of a boy of nine who during convalescence suddenly became ill with fever, rapid pulse and hurried respiration. A relapse of the disease was out of the question as the Widal reaction was over 1/2000. The ingestion of glucose in liberal quantities rapidly brought the patient to the normal.

Deafness.—This is a symptom about which the physician is frequently consulted as to prognosis. In the majority of cases, provided there is no actual lesion of the middle ear, the sense of hearing is not permanently impaired.

Infection by Asearis lumbricoides.—Though not strictly speaking a complication, this infection is apt to increase the gravity of the symptoms, particularly those of the nervous system, and, further, clinical observations suggest that such parasitic infection increases or prolongs the fever. Occasionally, when the temperature rises high, there is a spontaneous evacuation of worms. It is clearly desirable to remove the parasites, but the process involves some difficulty owing to the necessity of a free evacuation of the bowels. We make it a rule to examine the faeces of all patients admitted for typhoid, and if evidence of infection is discovered within the first week santonin and small doses of calomel are given. Later, we seize the moment when there is spontaneous looseness to give smaller and repeated doses of santonin without the addition of an aperient. It must be admitted that this form of treatment, though it appears harmless, is not always successful.

Kala-azar.—Finally, in a country where kala-azar is prevalent, the association of this disease with typhoid should be remembered (Rogers, 1910, and Napier, 1927) and the possibility of its supervention should be considered when there is an apparent relapse or when the period of fever is unduly prolonged.

THE ETIOLOGY AND TREATMENT OF RETINAL DETACHMENT

By E. O'G. KIRWAN, F.R.C.S.I.
LIEUTENANT-COLONEL, I.M.S.

Professor of Ophthalmology, Medical College, Calcutta

WITHIN the last five years detachment of the retina in all its aspects has interested the whole ophthalmic world and the importance of the subject led to its being chosen as one of the two main subjects for discussion at the recent International Congress of Ophthalmology at Madrid, at which I had the privilege of being present.

Etiology

Prevailing opinion still appears to be with Gonin who has taught that a hole or tear in the retina is the cause of detachment and that to cure this detachment it is all-important to localize the hole and occlude it by some means or other. If the operation is not successful in closing the hole or tear, the detachment recurs. His theory is however disputed by many, notwithstanding the fact that the principles underlying his method of cure have been generally admitted.

Shapland classifies holes and tears into five groups as follows:—

1. Round, oval, fenestrated, punched-out holes.
2. Arrow-head, and horse-shoe-shaped rents.
3. Disinsertions at the ora serrata.
4. Radial slit-like tears.
5. Irregular rents.

At Moorfield's Hospital, London, round and oval holes have been found to be the most common, with disinsertions at the ora serrata coming a good second, and arrow-head and horse-shoe shaped rents a close-up third. Slit-like tears and irregular rents are much less common.

Arruga (Barcelona) with a large experience of retinal detachments found the horse-shoe shaped hole to be the commonest.

The hole or tear may be single or multiple; in about 40 per cent of cases, round and oval holes are multiple and may be fenestrated. They vary in diameter from less than 0.1 mm. to 1.5 mm. The commonest position for these holes is in either of the temporal quadrants of the retina; they can occur in the nasal quadrants also, but far less commonly. They are situated from 1 mm. to 9 mm. with an average of 3 mm. distance from the ora serrata. Disinsertions at the ora serrata are more often single but can be multiple and occasionally occur in both eyes. They are usually situated on the temporal side of the retina and more commonly in the inferior temporal quadrant; they are very rarely found in the nasal quadrants. The arrow-head and horse-shoe-shaped rents are usually large and nearly always single, although they can be combined with other varieties of holes. They are situated usually above the

horizontal axis of the globe and are more often found in the temporal half than the nasal half of the retina. Round and oval holes are more commonly found in myopes and in high myopes more than in low; the same applies to the arrow-head and horse-shoe-shaped rents. Disinsertions at the ora serrata are more frequently to be found in emmetropes, less commonly in low myopes, and still less commonly in high myopes. How actually these holes or tears are caused is still a matter of conjecture. The round, oval, arrow-head, and horse-shoe shaped holes are produced according to Gonin by the traction of the degenerate vitreous stroma pulling on a small area of retina which has been involved in a previous inflammation. The small punched-out circular hole is most probably caused by a local patch of choroido-retinitis and the fenestrated holes are produced by localized retinal degeneration. The irregular-shaped tear and the disinsertion are not caused by diseases of the vitreous, but are definitely due to the results of direct or indirect trauma. The incidence of retinal detachment increases with age and about two-thirds of the cases occur in males. Fifty to sixty per cent of cases are found in myopes and about seventeen per cent are bilateral. Retinal atrophy and thinning are the most important predisposing causes and these are most probably due to a low-grade choroidal inflammation or tuberculosis.

Sourdille's theory of retinal detachment is that the situation of the pathological process is in the choroid coat of the eye, especially in the chorio-capillaris layer. This focus of infection causes a serous choroiditis with a collection of fluid between the two layers of the retina. Sourdille is of the opinion that a detachment is not necessarily always associated with a hole, and all that is necessary to cure the detachment is to let out the sub-retinal fluid and bring about an adhesive union between the retina and the choroid.

Schieck, Wessely and others consider that the tear or hole has not yet been proved to be the cause, but is a symptom of retinal detachment. Undoubtedly there are many cases of detachment in which a tear is not present and also there are holes in the retina without any detachment.

Dauids observed a case in which a hole was first seen and was followed later on by a detachment which grew in size. He considered that the retina was not detached by the entrance of vitreous alone through the hole but that the latter acted as an irritant and set up an inflammation in the choroid with the formation of an exudation, which gradually increased and detached the retina.

Jcandelize has brought forward a mixed theory of causation of retinal detachment. First a localized patch of inflammation occurs in the vascular choroid, leading to an exudation of serum between the pigmented and the

non-pigmented layers of the retina; later this is followed by a hole in the retina.

Arruga analysed the sub-retinal fluid in 38 cases. At first it showed a low albumen content and a low density, but later leucocytes, pigment cells, and an increase of the albumen were found. In old cases the density was again low; this was due perhaps to choroidal atrophy.

Lohcek experimenting on animals produced a retinal detachment by drawing up vitreous with a large needle and syringe, and maintaining suction as the needle was slowly withdrawn. He found that in the cases in which there was no tear the detachment healed spontaneously, in those in which there was an accompanying tear the detachment did not heal of its own accord as a rule, and that, in the few cases that reapposition did occur the tear healed, the margins of the tear becoming adherent to the choroid.

Blatt classifies retinal detachments into:—

1. The exudative type due to pregnancy, eclampsia, nephritis, tuberculosis, syphilis, diseases of the orbit and nasal sinuses. These should be treated along medical lines.

2. The idiopathic type associated with senility and myopia.

3. The traumatic type due to direct or indirect violence.

The last two types as a rule do not yield to conservative treatment and surgical interference by Gonin's method of ignipuncture or one of the other methods must be adopted.

Treatment

The first stage in the evolution of the surgical treatment of retinal detachment was largely due to the pioneer work of Professor Gonin. His operation consists in closing the tear or hole in the retina by cautery puncture after preliminary accurate localization of the hole. In Gonin's hands a cure has resulted in 55 per cent of cases, provided the operation is carried out within three weeks of the onset. In 15 per cent of cases a second ignipuncture was necessary and the results were good. In detachments of under one year's duration 40 per cent were satisfactory.

According to Gonin the following types of cases are unsuitable for his operation and these comprise a large number:—

1. Tears that are large and are situated too far from the ora serrata and close to the posterior pole of the globe.

2. Multiple tears.

3. Eyes which have semi-opaque or opaque media.

4. Patients who for some reason or other are unable to be kept quiet after operation.

Besides, the Gonin operation has many serious disadvantages, amongst which the most important are:—

1. Choroidal and subchoroidal hæmorrhages, also hæmorrhages into the vitreous.

2. Injury to the vitreous and the formation of traction bands.

3. Necrosis of the retina and the formation of scars.

4. Atrophy of the eye-ball.

Lindner agrees with Gonin that a detachment is accompanied by a tear in the retina and that the greatest proof of this supposition is that the detachment disappears as soon as the tear is occluded. Out of 118 cases, he found a tear in 84, and operating by Gonin's technique he got successful results in 38 per cent of cases.

Ophthalmologists of equal skill, presumably, have been unable to obtain the same high percentage of cures as Gonin. Owing to this and the difficulty, as well as the uncertainty in localizing the tear and to the fact that often a tear cannot be found, ophthalmologists have been led to adopt other surgical procedures to obtain more successful results.

The second stage in the evolution of the surgical treatment of retinal detachment was largely due to the work of Guist and Lindner. They used a method devised by the former, and now known as the Guist operation. The purpose of this method is to set up a localized inflammation in the choroid by chemical means, resulting in the adhesion of the detached part of the retina to the underlying inflamed choroid and closure of the retinal tear. The inflammation in the choroid should be limited to the whole area of detached retina.

The Guist operation is performed under the usual local anæsthesia and consists in making a series of holes in the sclera over the exact area of the tear with a 1.5 mm. Elliot trephine. If necessary, a muscle may be temporarily divided to expose the part of the sclera required. These trephine holes should be placed not more than 1.5 mm. apart and should not go completely through the last thin layer of the sclera for fear of injuring the choroid. This layer is removed later with the point of a fine Graefe knife or keratome. The trephine holes should completely surround the tear and a series should also be made in the line between the detached and non-detached retina. As many as 24 trephine holes can be made. The choroid exposed through these holes is then cauterized with a fine pencil of potassium hydrate for a second, and immediately afterwards the area is neutralized with a half per cent solution of acetic acid and then irrigated with normal saline. After the cauterization has been completed, the sub-retinal fluid is allowed to escape by perforating the choroid through a number of the trephine holes with a lacrimal probe, so that the retina and choroid can come together and become adherent. The after-treatment is most important and is much the same as the post-operative treatment following the Gonin operation. Complete rest in the recumbent position for 7 days, and, as far as possible, the maintenance of the patient's head in such a position

that the vitreous rests on that part of the retina with the tear. Both eyes are kept bandaged for about a week, and later, stenopœic glasses are worn for a month or 6 weeks.

At the annual meeting of the German Ophthalmological Society in 1932 at Leipzig, Guist reported 77 per cent of his uncomplicated cases, 61 in number, as cured. In eleven complicated cases such as those accompanied by retinitis proliferans, irido-cyclitis, etc., he reported two successful cures. In seven patients with a detachment of four months' duration and who had previously been treated unsuccessfully by Gonin's operation, four gave successful results. In 17 patients with a retinal detachment of eight months' duration and who had also been previously treated by canthary puncture, two were successful. In 13 aphakic eyes with retinal detachment, five gave successful results. Guist's total average of successful results was 56 per cent.

Lindner in 1931 reported a series of 19 patients in whom he got 68 per cent of successful results.

The advantages of the Guist operation are :—

1. Exact localization of the hole or tear is not required.
2. Complications are not so frequent and severe.
3. There is no scarring of the retina and damage to the vitreous.
4. It is sometimes successful in cases in which ignipuncture has failed.
5. In old-standing cases and in cases in which tears are not found, it is sometimes successful.
6. In multiple tears, large tears, marked hypertension, it is more often successful than Gonin's method.

The disadvantages of the operation are :—

1. The time taken to carry out the operation which may be anything from one to two hours.
2. The danger of penetrating the choroid with the trephine and the loss of the sub-retinal fluid rendering continuance of the operation impossible owing to hypotony.
3. The danger of bleeding with the occurrence of intra-ocular hæmorrhage; this can largely be prevented by taking care to avoid the venæ vorticosæ.

The third stage in the evolution of the surgical treatment of retinal detachment was largely due to the work of Larsson, Weve and later Safar. They employed diathermy to close the tear in the retina and considered it was a simpler and less dangerous procedure than other methods. The purpose of their method is, like the Guist operation, to set up an adhesive choroiditis, but by diathermal applications rather than by chemical irritation. As a result, the detached portion of the retina becomes adherent to the underlying area of inflamed choroid and the retinal tear becomes occluded.

They like Gonin, Lindner and Guist are also of the opinion that the tear must be closed if the operation is to be a success.

The methods of electro-diathermy as used by Larsson, Weve, and Safar differ in their technique. Larsson uses multiple superficial diathermy. The active electrode is applied to the surface of the sclera and consists of a fine metal rod of 1 to 2 mm. thickness. The current should not exceed 150 milliamperes and should be controlled by a foot switch. As soon as the area of sclera under treatment shows a greenish-grey discoloration, the current should be turned off and the electrode removed. This usually takes from 3 to 5 seconds. A series of these electro-coagulation areas are made on the sclera at a distance of 3 millimetres from each other and the hole encircled, or if the tear is at the ora serrata a semi-circular line of applications is made over the affected area parallel to the limbus. The sub-retinal fluid should be carefully dealt with in the same way as in the Guist operation. Larsson has reported 40 cases treated by this method in which 20 cases gave excellent results. He considers that cure is brought about by tissue reaction and that, on account of the adhesions between the detached part of the retina and the underlying choroid over a large area, recurrences of detachment are less common. Intra-ocular hæmorrhages are uncommon owing to the coagulation of the blood-vessels and there is no trauma to the vitreous. In this method, like that of Guist, exact localization of the tear though advantageous is not essential.

Larsson's method of superficial diathermy is now popular in England and at Moorfield's Ophthalmic Hospital, London, it is the routine method of surgical procedure for retinal detachment; the results are more satisfactory than those following the Gonin ignipuncture operation. The high-powered diathermy apparatus, permitting very rapid sparking with low current intensity, which is necessary for electro-coagulation, is made by John Weiss & Son, London, and is now being used in the Eye Infirmary Medical College, Calcutta, and in the Government Ophthalmic Hospital, Madras.

Weve combines surface diathermy with multiple diathermal electro-punctures, or uses one or other method separately. The electro-puncture procedure consists of penetrating the sclera and choroid with the active electrode which has a sharp pointed terminal. Weve emphasizes the importance of preliminary exact localization of the hole or tear. The current should not exceed 50 milliamperes and the time of application varies from one to five seconds according to circumstances. He uses superficial diathermy for cases in which there is a tear at the ora serrata and for flat detachments and the electro-puncture procedure for cases in which there is much ballooning of the retina and old-standing cases of retina detachment. Weve reported 23

cases treated by diathermy coagulation, of which 11 showed satisfactory results.

More recently, Weve, using a uni-polar electrode and a current of only a few milliamperes, has been localizing the hole in relation to a micro-puncture by immediate ophthalmoscopy.

Safar has been working on much the same lines as Weve and has introduced a variety of different electrodes with one or many needle points, 2 mm. long. He also uses his minute 'nails' which he implants in the selected area of the sclero-choroid by holding them in an insulated forceps and pressing them against the sclera with the terminal of the active electrode. A series of these 'nails' are arranged in a circle around the hole, or in the form of a semi-circle if the tear is at the ora. The 'nails' should be about 3 mm. apart and should be left in position until the requisite number of punctures has been made. In cases in which a tear or hole cannot be found a retinal detachment can often be cured by applying diathermy punctures in that part of the retina in which the detachment commenced. The 'nails' are removed together and the sub-retinal fluid allowed to drain away. It is important to see that this fluid has escaped so that apposition of the retina and choroid takes place, resulting in adhesion of these two layers and closure of the hole. To cure a retinal detachment Safar like many others considers it is necessary to produce an inflammation in the choroid in the region of the retinal tear but the injury to the retina and choroid should be as little as possible. This is best accomplished by diathermy puncture, as it produces minute scars such as are seen in mild choroiditis.

Up to 1932 Safar has reported 39 unselected cases treated by diathermal micro-puncture and has had 24 successful results.

At present it would appear that electro-coagulation by diathermy will be the method of choice in the future for the treatment of retinal detachment for the reason that its application can be modified and its dosage graduated. Whatever line of treatment is adopted it should always be remembered that the three important factors are—irritation to produce an adhesive choroiditis, evacuation of the sub-retinal fluid, and rapid reattachment of the retina to the choroid.

Careful preliminary examination of each case, localization of the hole or tear, and strict attention to detail at the time of operation and the after treatment are necessary if the best results are to be obtained. At the same time I would like to emphasize the fact that however carefully the measurements to localize the hole are made they are bound to be inaccurate; and also it is possible to be either too conservative in treatment or actually to do too much. Both result in partial improvement or no improvement, the

(Continued at foot of next column)

PRIMARY CARCINOMA OF THE GALL-BLADDER

By VISHWA NATH, M.A., M.D., F.R.C.P.I.

D.P.H., D.T.M. & H.

Department of Pathology, King Edward Medical College, Lahore

A. S., a Sikh, aged 48 years, was admitted to the Mayo Hospital, Lahore, on the 20th of July 1932, suffering from ascites, oedema of the lower extremities and jaundice. He complained of pain in the right hypochondrium which was also tender to palpation. The duration of the disease was stated to be six months, during which time the patient had gradually but progressively grown worse. The total white blood cell count was 13,000 per c.mm. of which 85 per cent were polymorphonuclear leucocytes. Blood films showed no parasites. Fever and cholæmic symptoms were present and the latter increased rapidly. The patient died on the 24th of July—4 days after admission to hospital. Throughout his stay in hospital he suffered from retention of urine which had to be relieved by catheter.

The clinical diagnosis was malignant disease of the liver.

At autopsy I found a tall emaciated Sikh, intensely icteric, presenting the appearance of 'black jaundice'. The abdomen was greatly distended with fluid and the lower extremities and scrotum tense with oedema. No enlargement of supra-clavicular lymphatic glands was found.

No naked-eye abnormality was detected in the lungs or tracheo-bronchial and mediastinal glands. The heart presented no abnormality except for two 'milk spots' on its anterior surface.

The peritoneal cavity contained 8 pints of intensely bile-stained fluid. The peritoneum, both visceral and parietal, was found to be free from localized or diffuse thickening.

The liver was not enlarged; it was soft, almost diffuent, and of deep-green colour. Its surface was slightly wrinkled; but no surface abnormality indicative either of cirrhosis or a new growth was seen.

The gall-bladder was felt to be hard; this was due to marked thickening of its wall. It was difficult to separate it properly, its neck, the cystic and common bile ducts and the head of the pancreas being all parts of a hard mass, so the stomach was ligatured off and separated at the pyloric end, and the duodenum similarly separated off the jejunum at its distal end.

(Continued from previous column)

former from the production of irritation insufficient to cause an adhesive choroiditis, the latter from too much inflammatory exudate poured out between the retina and the choroid.

The liver, the gall-bladder, the pancreas and the duodenum were then removed together.

The cut surface of the liver was deep green to greenish brown in colour and showed no cirrhotic or neoplastic change. The gall-bladder was somewhat adherent to the fossa where it is lodged on the liver, but there was no grossly observable neoplastic change in the contiguous hepatic substance.

The gall-bladder was then opened. It contained only a small amount of thick viscid greenish bile. No gall-stones were found. Its fundus was found to be the seat of an infiltrative growth which projected noticeably into the

Section of the liver showed dilated bile ducts and a relative increase of pericholangitic connective tissue. Small areas of necrosis of liver parenchyma were also in evidence.

Sections were taken from different parts of the new growth in the gall-bladder, and from the mass involving the head of the pancreas and the cystic and sub-pyloric glands. Sections from the growth in the fundus show it to be a squamous-celled carcinoma, exhibiting typical flat squamous cells (figure 2) and sections from the mass involving the head of the pancreas show a typical scirrhus carcinoma with considerable fibrosis and islands of spheroidal cells.

Fig. 1.—A. Portion of liver. Green and wrinkled. B. Thickened gall-bladder showing growth in the fundus. C. Duodenal mucosa covering the tumour mass involving the head of the pancreas. D. Portion of tumour mass.

Fig. 2.—Photomicrograph from a section taken from the growth in the fundus, showing squamous cell metaplasia.

viscus on a sessile base (figure 1). It showed no strict delimitation but faded away into the much-thickened wall of the viscus. The growth diminished in hardness as you approached towards the neck, where it was soft and friable, and extended into and almost obliterated the cystic duct. The common bile duct could not be dissected out. It was imbedded in a hard mass into which were fused the lymph glands of the porta hepatis and also the head of the pancreas. The duodenum was firmly adherent to the mass, but its lumen was free from any nodule or ulceration indicative of mucosal involvement.

There was no evidence of malignant disease of the peritoneum and no marked enlargement of mesenteric lymph glands. The ascites was evidently due to pressure of the growth on the portal vein and not to malignant peritonitis. The stomach and the intestines showed no abnormality and the examination of the spleen, genito-urinary and nervous systems also gave negative result. Careful naked-eye examination of different viscera failed to show any secondary deposits.

Histological examination showed nothing of pathological interest, except in the liver and the parts involved in the new growth.

A large hyperchromatic cell is seen near the centre (figure 3).

Fig. 3.—Photomicrograph showing masses of spheroidal cells enclosed by mature fibrous tissue.

Evidently this new growth had its origin in the fundus of the gall-bladder and extended therefrom to the common bile duct and the head of the pancreas. Although the pancreas is more commonly the seat of primary carcinoma and secondary growths in it are rare, primary carcinoma of the head of the pancreas leads, according to Courvoisier's law, to a much dilated and

thin-walled gall-bladder, which was not a feature of this case. Metastases very commonly occur from a pancreatic carcinoma in the liver and the peritoneum; there were no metastases in this case. I have also been unable to find mention of any case in the available literature where a primary carcinoma of the head of the pancreas had extended to the gall-bladder and showed squamous metaplasia in that situation.

On the other hand squamous metaplasia in primary carcinoma of the gall-bladder, though not of common occurrence, is met with not infrequently and the same may be said of secondary involvement of the pancreas in primary carcinoma of the gall-bladder. In the gall-bladder too, like the pancreas, it is primary carcinoma which is the commonest growth and the fundus its commonest site. Ewing (1928), quoting Musser, gives an analysis of one hundred cases of primary carcinoma of the gall-bladder in which the liver was found involved in 54, abdominal lymphatic glands in 16, lungs or pleura in 10 and pancreas and adrenals occasionally.

Besides these two uncommon features, squamous metaplasia and involvement of the pancreas, the case under discussion also showed no metastases in the liver and no gall-stones. This last feature deserves special consideration. The association of gall-stones with cancer of the gall-bladder is considered to be very intimate. It is regarded as an important illustration of the rôle of chronic irritation in the production of cancer. Graham (1931) says cancer of the gall-bladder is not a rare disease but forms 8 to 10 per cent of all carcinomata and, on the basis of the gall-stones gall-bladder-cancer relationship, recommends early removal of the viscous in all cases of cholelithiasis. Leitch (1924) states that over 10 per cent of adults have gall-stones and that 5 per cent of these develop cancer of gall-bladder. He asserts that gall-stones are present in practically all cases of cancer of the gall-bladder. Ewing (1928) quotes Musser as saying that gall-stones are found in 69 per cent of cases who have cancer of gall-bladder, and Janowski puts it at 100 per cent. Watts (1922) in the study of a series of 525 operations on the gall-bladder found primary carcinoma in 20, i.e., 3.8 per cent, and of these 20 cases gall-stones were found only in 10.

Osler and McCrae (1926-28) state that in the Massachusetts General Hospital, Boston, U.S.A., of 2,631 operations performed on the gall-bladder during 30 years, 63, i.e., 2.4 per cent, showed primary carcinoma of the gall-bladder and in these latter only 36 per cent showed gall-stones.

In the Mayo Hospital, Lahore, of a series of 129 operations done on the gall-bladder, 92 showed gall-stones and 11 were found to have carcinoma, but in the latter number presence of gall-stones was recorded only in 2. Of these

NEPHROLITHIASIS OF THE HORSE-SHOE KIDNEY

By P. N. RAY, B.A., M.B. (Cal.), F.R.C.S. (Eng.)
Hony. Junior Visiting Surgeon, Calcutta Medical
College Hospitals

By the term horse-shoe kidney is meant the fusion of the kidneys across the vertebral column. The band of union, or the isthmus, passes commonly between the lower and rarely between the upper poles across the abdominal aorta and the inferior vena cava. The isthmus varies from a band of fibrous tissue to a definite bridge of renal parenchyma. According to statistics compiled from the post-mortem room, the incidence of the horse-shoe kidney varies from 1 in 1,590 to 1 in 500 cases (0.06 per cent

(Continued from previous column)

11 cases 7 showed metastases in the liver and one showed extension to the stomach. In addition there was one case of malignant disease of the common bile duct.

Seven out of the above 12 cases of cancer were females and 5 were males. The average age incidence was 39.7 years, the limits being 30 and 55 years.

Of the 92 cases of cholelithiasis 29 were Europeans and 63 were Indians. The average age of patients in the former group was 40 years and in the latter 32.6 years. In the former group there were 22 females to 7 males, and in the latter 48 to 15.

In the Indian group, 41 cases were amongst Hindus—30 females and 11 males, 19 amongst Mohammedans—16 females and 4 males, and two amongst females of other communities. In spite of their lower numerical strength in the population the higher incidence of cholelithiasis amongst Hindus may be related to their fat-rich dietary.

It has been suggested that in cases of carcinoma of gall-bladder where no gall-stones are found the stones may have passed out, or that metabolic and infective factors causing mural irritation in that viscus may even in the absence of gall-stones lead to cancer. Squamous metaplasia probably indicates a more persistent operation of the irritant than that which obtains in forms of carcinomata representing cellular structure more closely allied to the lining epithelium of the viscous.

to 0.2 per cent). In cases of renal calculus alone, there were 12 cases of horse-shoe kidney out of a total of 981, or 1.3 per cent (July, 1929). As would be expected, surgical statistics show a much higher ratio, because pathological changes are more likely to occur in the abnormal kidney. The following statistics have been compiled from the post-mortem examination records of the pathological department of the Calcutta Medical College and hospitals.

Total number of post-mortem examinations—1,513 (1916–32).

On examination.—No definite signs could be elicited. Micturition was painless; frequency, 6:2; character of stream, good.

Tongue, moist and coated. Of average build, poorly nourished. Temperature—normal, Pulse and respiration—80 and 22 per minute respectively.

Examination of urine

Specific gravity, 1016.

Reaction, slightly alkaline.

Albumen, faint trace.

Microscopic examination, triple phosphates.

ABNORMALITY

Kidney	Lobulation	Solitary	Horse-shoe	Fusion anomaly	Ectopic
Right ..	6	3	2	1 (2 ureters opening into bladder)	1
Left ..	8 (Both kidneys 6 times)				

There were, thus, two cases of horse-shoe kidney in a series of 1,513 (or 0.13 per cent). It is to be noted that in this series there was not a single instance of nephrolithiasis in an abnormal kidney.

An analysis of the registrar's records of the Calcutta Medical College hospitals during the period 1930–32 shows that the total number of nephrectomies and pyelo- or nephrolithotomies was 33. This number did not include any case of horse-shoe kidney. In comparison with European and American statistics, the infrequency of nephrolithiasis of the normal, as well as of the abnormal, kidney in Calcutta is worthy of note. On account of the rarity of nephrolithiasis of the horse-shoe kidney and the presence of other interesting anomalies, the following case appears to be worthy of record.

Present case

J. N. C., male, aged 47, was admitted into the Prince of Wales hospital on 26th June, 1933, on account of recurrent attacks of pain in the left loin and back, shooting down into the scrotum and the upper part of the thigh.

History of the present illness.—The first attack of pain occurred in 1929, but there was pain on both sides. The patient gives a history of sudden obstruction of urine later in the year. During the year 1930, there were two attacks of painful hæmaturia at an interval of about six months. In 1931, some white deposit was noticed in his urine for the first time. The pain on the right side disappeared suddenly, but it became agonizing on the left side.

History of past illness.—No history of syphilis or gonorrhœa.

Family history.—There was no history of calculous disease in the parents or near relatives.

Examination of blood

Hæmoglobin, 80 per cent.

Leucocytes, 6,600 per c.mm.

Polymorphonuclears, 52.

Lymphocytes, 40.

Large mononuclears, 0.

Eosinophiles, 8.

Fig. 1.—Skiagram showing the presence of a calculus in the pelvis of the left kidney.

Urea concentration test

No. I specimen, 1.6 per cent.

No. II specimen, 2.4 per cent.

No. III specimen, 2.8 per cent.

No. IV specimen, 3 per cent.

Blood urea.—0.03 per cent.

Chromocystoscopy (indigo carmine).—Excretion of the dye only by the left ureter. No excretion by the right ureter within 15 minutes.

Skiagraphy of the urinary tract.—A solitary stone was seen in the pelvis of the left kidney.

Excretion urography (Uroselectan B).—It is seen from the skiagrams that the lower poles of both the kidneys are pointing inwards. This appearance is present in the horse-shoe kidney.

Fig 2—Excretion urography (5 mins) The outline of the calculus is overlapped by the nephrogram on the left side.

The left ureter is lying on the outer side of the kidney. The right ureter is not seen. A calculus is seen within the pelvis of the left kidney, which appears to be excreting more than the right.

Diagnosis.—Nephrolithiasis of a horse-shoe kidney with imperfect function of the right side.

Treatment

(a) *General.*—Careful general treatment was undertaken in view of the imperfect function of the right half of his kidney and an attack of influenza during his stay in the hospital.

(b) *Operative.*—An extraperitoneal lumbar incision was made. The diagnosis of horse-shoe kidney was confirmed by tracing the isthmus from the lower pole across the vertebral column in front of the aorta and the inferior vena cava. The ureter was next identified. It was abnormal in position. It was found to come out from the posterior surface, and a little lower down it was crossed by an aberrant artery. Pyelolithotomy was performed and the calculus was extracted intact. The incision was left open and a drainage tube was inserted. The wound was next closed in the usual way.

Convalescence was uneventful with the exception of a mild attack of broncho-pneumonia. The patient was discharged cured on 2nd October, 1933.

Commentary

With regard to the differential diagnosis, the following conditions had to be considered—(a) Bilateral nephrolithiasis, with obstruction of the right ureter. (b) Calculus in a solitary kidney. (c) Other abnormal conditions. On skiagraphy of the urinary tract, the first of these conditions was excluded. The correct diagnosis was made with the help of excretion urography. The correct assessment of renal function however is beset with many difficulties. In my experience chromocystoscopy is found to be a much more reliable method than the urea concentration test. The excretion of uroselectan B is a reliable index of the physiology of renal secretion. Before the days of excretion urography, a pre-operative diagnosis of horse-shoe kidney was comparatively infrequently made. There is no syndrome of symptoms and signs, characteristic of the horse-shoe kidney. Consequently, great difficulties are occasionally met with in diagnosis, in spite of the recent methods of investigation. In this connection, it is of interest to consider a case recorded by Dunhill (1932) of which the writer had personal knowledge in St. Bartholomew's Hospital, London:

A young man, aged 24, was admitted with the history of a sudden attack of pain beginning in the

Fig 3—Excretion urography (15 mins) The outline of the horse-shoe kidney is well shown.

hypogastrium and radiating to the right lumbar region. Skiagraphy did not reveal anything abnormal. An appendicular abscess was suspected. An operation was performed outside but the appendix was found to be normal, and a small swelling was palpated. On excretion urography, the left renal pelvis was outlined but

no shadow was seen on the right side. The diagnosis of a right-sided hydronephrosis was made. Nephrectomy was performed and it was then realized that a horse-shoe kidney was present. The presence of purulent infection inhibits visualization by excretion urography.

In course of my post-graduate work under Prof. von Lichtenberg of Berlin, I had the good fortune to study a remarkable series of excretion urograms. The visualization of the isthmus of the horse-shoe kidney was a striking feature. This is due to the nephrogenic possibilities of excretion urography (von Lichtenberg and Swick, 1929). By means of an excretion urogram this anomaly is more easily diagnosed. The important diagnostic features are given below (von Lichtenberg, 1931):

(a) The bending of the lower kidney pole towards the vertebral column.

(b) The pelvis and calyces are of a bizarre shape.

Fig. 4.—Excretion urography (30 mins.). The left ureter is visualized. The left half of the kidney appears to function better than the right.

(c) The 180 degree turning of the one or the other side, and the unusual course of the ureter.

With regard to treatment, there is little doubt that an aseptic calculus lying in one side of a horse-shoe kidney is best removed as soon as possible. Treatment is much more difficult, when infection is present. It is believed that infection spreads more rapidly from one organ to the other in the case of horse-shoe kidney than when the two kidneys are separated. In the latter case, infection is always carried by the blood stream from one kidney to the other, but in the former it may spread across through the isthmus. Bilateral calculus means infection first on one side and then on the other (Ball and Evans, 1932). If infected calculi are found

on both sides, they may be removed through the pelvis, if they are small. If large branching calculi are present in both halves, or if numerous stones are scattered throughout the fused kidney, it is usually impossible to remove the calculi. In case of pyonephrosis, drainage is indicated.

The difficulties and complications of the operation are dependent to a large extent on the accessibility and vary indirectly with the degree of fusion. The pelvis is generally markedly irregular in size and shape. It is flattened out over an extensive area on the anterior surface of the kidney. The ureter usually passes in front of the isthmus, but occasionally also behind it (Judd, Braasch and Scholl, 1922). The presence of anomalous blood vessels greatly increases the risk and difficulty of surgical procedures. The arterial branches enter the parenchyma mostly behind the pelvis (Jeck, 1932). The arteries come from the aorta either in one common trunk arising below the mesenteric arteries with several smaller branches from the iliac arteries, or else two separate trunks, similar to the normal renal arteries, only at a lower level. Besides these, however, there are nearly always smaller twigs coming from below and behind, arising from the external and internal iliac vessels.

The special features of the case reported in this paper are as follows: (i) on chromocystoscopy there was no excretion of the dye by the right ureter within 15 minutes; (ii) the diagnosis of a horse-shoe kidney was made with the help of excretion urography, the left ureter being found to lie on the outer side of the kidney, and the left kidney appearing to excrete more than the right; (iii) at the time of operation it was noted that the ureter was lying posterior to the isthmus, where it was crossed by an abnormal artery. Similar anomalies of the pelvis and ureter are also rarely met with in the case of ectopic kidneys. Such a kidney has recently been described (De, 1933), in which the pelvis is situated laterally and anteriorly.

The stone was removed by pyelolithotomy and the patient made a complete recovery. From the history of recurrent attacks of pain on both sides and subsequent cessation of pain on the right side, it may be inferred that stones were present at first on both sides. It is not clear why there was imperfect function on the left side. It would be interesting to investigate the subsequent function of the left kidney. The patient has been advised to attend the hospital for a cystoscopic examination at the end of six weeks. If necessary ureteric catheterization and ascending pyelography may be performed. With regard to prognosis, recurrence of nephrolithiasis is not unusual. It is a remarkable fact that kidneys which show a developmental defect are much more prone to stone and other diseases than the normally

(From the King George Hospital, Vizagapatam)

THOUGH the last word on the ætiology of beri-beri has not yet been said, it is generally accepted by clinicians, experienced in this disease,

(Continued from previous page)

developed organs. The high implantation of the ureter and the sharp uretero-pelvic angle, which prevent free drainage, are the most common causes of disease in these kidneys. Consequently it is explicable why recurrence of stone is usual. The prognosis is worse in the case of infected calculi. From an analysis of the records of the Calcutta Medical College hospitals, the infrequency of nephrolithiasis is very striking. A rare case of calculous hydronephrosis in a horse-shoe kidney in an Indian female was described by Marchant (1931). The diagnosis however was made during operation.

Summary

(1) A case of nephrolithiasis of the horse-shoe kidney with interesting anomalies has been described.

(2) In this connection the surgical records of the Calcutta Medical College hospitals for the last three years and the post-mortem records for the last 18 years have been investigated and are summarized.

(3) A pre-operative knowledge of the existence of a horse-shoe kidney is a great advantage, owing to the dangers and difficulties caused by the various anatomical anomalies.

I wish to express my gratitude to my senior colleague Professor L. M. Banerjee for his kind permission to publish this case. My best thanks are due to Dr. M. N. De, Professor of Pathology, for his kindness in giving me free access to the hospital records, to Dr. G. Galstaun, the honorary radiologist, for the excellent skiagraphy, and to Dr. R. R. Roy, our senior house surgeon, for his valuable help.

that the avian polyneuritis induced by avitaminosis is not clinically identical with human beri-beri. Megaw (Megaw and Rogers, 1930), after enumerating at length the debated points with reference to the ætiology, added that he did so in the hope that some readers might seize any opportunity, which came their way, of making contributions to the knowledge of beri-beri. We have had the opportunity of observing, during the past few months, a variety of polyneuritis occurring in women during the puerperium. The neuritic condition that is described below appears to be the only condition, occurring in an endemic area, that bears any resemblance to the well-recognized syndrome of beri-beri. An attempt has been made here to find out (a) if this polyneuritis is a variety of beri-beri endemic in the locality, (b) if so, what are the special ætiological factors that determine it, and (c) if not, what exactly the condition is.

Other records of puerperal polyneuritis.—Peripheral neuritis as a complication of the puerperium or of pregnancy has been noticed by some, though it is not a recognized complication or sequel of pregnancy or the puerperium, such as are eclampsia, toxæmic kidney, anæmia and hyperemesis. Wilson and Garvey (1932), while drawing attention to three other presumable toxæmias of pregnancy, i.e., psychosis, impetigo gestationis and certain types of multiple polyneuritis, described three cases of polyneuritis gravidarum in the later weeks of pregnancy. They hold the view that ordinarily the symptoms subside with the puerperium in cases where they start during the later months of pregnancy. Having had only three cases, they observe that, while the condition of polyneuritis has been recognized as a complication of pregnancy and the puerperium for a long time, it occurs not very frequently in the severe forms, and no one person has had the opportunity of observing a large series of cases.

Churchill (1854) discussed the possibility of this condition being of a toxic nature, after collecting 33 examples. Most of his cases showed albuminuria, which lent support to the idea that it was a toxæmia of pregnancy.

Mopuss (1887) reported seven cases of peripheral neuritis all occurring in the puerperium and with no associated general disturbance.

Lindeman (quoted by Wilson and Garvey, 1932), in fatal cases of this type, found at autopsy, in addition to lesions of various peripheral nerves, fatty degeneration of the liver and cloudy swelling and degenerative changes in the kidneys. Similar lesions were found in the liver and kidneys of the fœtus.

Von Hosslin (1905) collected 94 cases, from the literature and his own experience. His series included all types, in some only a single nerve being involved, in others groups of nerves, while still others were of the severe type with progressive general paralysis, vomiting and

mental disturbances. In cases with generalized paralysis the mortality was 20 per cent. Von Hosslin did not advocate termination of pregnancy as a necessary means of alleviating the condition. In not a few patients the first symptom appeared in the puerperium, several days after the pregnancy had come to an end.

Among the more recent series is that reported by Albeck (quoted by Wilson and Garvey, 1932) who presented 9 cases of the severe type, with vomiting, psychosis and progressive paralysis. In 7 of them pregnancy was interrupted; all apparently recovered though the convalescence was prolonged and months elapsed before normal muscular function was restored.

Seitz (1892), having excluded all other possible causes, regards the disease as of toxic origin. Only in cases of suspected optic or phrenic nerve paralysis was interruption of pregnancy called for. He cites a case of A. Mayer's treated successfully during pregnancy by the injection of 10 c.cm. of serum from a healthy pregnant woman.

Wilson and Garvey (*loc. cit.*) attempted to study the changes which occur in the general metabolism of such patients. Their cases, that are the most recent to come to our knowledge, are of the following nature. Extensive polyneuritis was associated with pregnancy in its later stages. At the onset of the illness severe and persistent vomiting was noticed with profound mental disturbances. They were satisfied that such toxic agents as alcohol, lead, and infection had no ætiological bearing in these cases. They further said that it was impossible to make any definite statement in regard to the exact ætiology, and for the present the condition must remain in the category of unsolved problems, in common with other toxæmias of pregnancy. They noticed in these cases a peculiar disturbance of the general metabolism characterized particularly by a high carbon dioxide combining power and low blood chlorides. The findings were suggestive of alkalosis. None of these women had any alkaline medication during their illness. None showed any appreciable respiratory disturbances. All had persistent vomiting prior to admission. In the presence of defective elimination alkali might still be retained, and the CO_2 combining power then would remain high. The authors go so far as to offer the suggestion that vomiting was not alone the cause of alkalosis.

Recently other workers in this part of India have observed this condition though they have only made a passing reference to it. Kamath (1931), whose observations are from this very area, when discussing the diverse conditions associated with polyneuritis said that the puerperal period is often complicated by this condition. 'It may also be noted', he said, 'that the puerperium may predispose to beri-beri. In the Circars, beri-beri by a transferred epithet is called "Suthika", which literally means the

puerperal period'. Raman and Mahadevan (1930) while studying beri-beri in the neighbouring district of Guntur recorded that the incidence amongst males was higher at all ages except between 15 and 20. In most cases in women the ailment is subsequent to the first childbirth. They give the clinical picture of fever of a few days duration, weakness of the lower extremities, œdema of the calf muscles, and tenderness and anæsthesia of the legs with loss of knee jerks. They recorded five cases of post-puerperal neuritis in 18 months. This, according to them, is different from beri-beri occurring in pregnant women. The symptoms were weakness of both the legs and inability to walk, coming on three or four weeks after pregnancy. In all these cases there was a slight white discharge from the uterus. Col. Hingston suggested sub-involution and sepsis as the cause of the condition, as the patients got well when the discharge stopped.

The present series.—In our series of 24 cases, observed during fifteen months, there was discharge from the uterus in only one case, and no septicæmia or toxæmia. The infant was invariably nursed by the mother and grew satisfactorily.

TABLE

Cases of polyneuritis admitted into the medical wards during the past fifteen months

Sex and condition	Number of total admissions	Number of cases of polyneuritis	
Males ..	1,737	54	About 3 per cent.
Females ..	415	24 } Puerperal.	About 6 per cent.
		3 } Non-puerperal.	Under 1 per cent.

The mean age of the 24 cases of post-puerperal polyneuritis was 28 years, the youngest was 16 and the oldest 50. Ten of these were primiparæ. There was one death, and 15 were relieved of their symptoms at the time of discharge.

History and clinical picture.—The typical history of a woman admitted for polyneuritis during the puerperium was as follows. The woman went through her period of pregnancy and labour without any untoward event. She had been on a special diet for a fortnight after labour, but from the history there was nothing to suggest any noxious dietetic principle likely to cause polyneuritis. About two to three months after the labour, the patient had subjective symptoms of tingling shooting pains, cramps, etc., in the legs, often severe at night. About 30 per cent of cases gave a history of general anæmia and fever for about ten days preceding the attack of neuritis. Later, there

was weakness of the legs with inability to walk without help. The feeling extended to the upper extremities in more than 50 per cent of the cases.

On admission, a distinct wasting of the muscles of the lower extremities was noticed, with the feet in the drop position. The calf muscles were tender. Deep reflexes were lost. The soles were hyperæsthetic and a flexor response was elicited in most cases. The abdominal reflexes were always present. The patient occasionally complained of heaviness in the chest, but had no appreciable dyspnoea at rest or on moderate exertion. A few patients showed œdema of the legs persisting after the original anasarca had disappeared.

The infants in about seventy per cent of the cases were alive and healthy, with the mother suckling them. The temperature was normal, but the pulse was invariably in the neighbourhood of 100. The blood pressure was normal in sixty per cent of cases, moderately raised in the rest. The heart was normal on physical examination, and the urine had no albumin.

For comparison with this picture that of cases of 'beri-beri' admitted on the male side about the same time is given. Sturdy well-built men, between 30 and 45 years of age, were admitted with diffuse œdema over the neck, chest and limbs, and complaining of cramps and tingling in the extremities. The patients were often dyspnoic, though they preferred the recumbent posture. On physical examination, the heart was often found enlarged, and the sounds feeble or replaced by a murmur. The blood pressure showed a distinctly low figure for diastole and often for systole as well. In about half the cases treatment with minute doses of adrenalin was of no avail. With the others, rest and adrenalin with vitamin B in the form of Bemax, yeast, marmite, germinating 'gram' or toddy had a delayed but satisfactory effect.

Diet: The diet of an average individual admitted with signs and symptoms of polyneuritis did not materially differ from the diet of the patients in the ward who were not suffering from this disease; the proportions of carbohydrate, protein and fat work out roughly at 10:2:1.

Discussion.—A study of the literature on polyneuritis shows that it is not a recognized complication of the puerperium.

Other possible coincident factors to account for this ailment were absent, such as alcohol, lead, arsenic, mercury, organic or vegetable toxin. There is the possibility of auto-intoxication. Apart from our failure to detect such a source, polyneuritis of the puerperium has not been observed in such numbers anywhere else, as far as our knowledge goes, except in one other area, referred to below, where beri-beri is endemic.

It is then to be decided if the condition is a variety of beri-beri and if so what causes the

high incidence during the puerperium. There is evidence for the assumption that the condition—be it a toxæmia, toxi-infection or vitamin lack—tends to assert itself as a neuritis after devitalizing states, such as fever, or in a woman after the strain of pregnancy, parturition or lactation. Often the first pregnancy was the inauguration of this symptom-complex. Grey (1928), while investigating the 'pre-beri-beri' condition with special reference to its existence in Japan, observed that in any deficiency disease two conditions are essential, *i.e.*, the accessory factor and the factor to which it is accessory. Though an adequate supply of vitamin B may hide the ill-effects of an unbalanced diet there must be an underlying weakness in the organism and this may suddenly become manifest when the vitamin is withheld. Such an underlying weakness might be expected to develop into true beri-beri without any diet changes merely as the result of adverse conditions such as excessive heat or humidity, lack of exercise, fatigue, and super-added intoxication—and pregnancy, if we may add to his list.

Acosto-Sison (1928) while investigating neuritis in the Philippines noticed that it was quite common among the Philippine parturients. Many of his co-workers held the view that the condition was beri-beri. The babies of mothers so affected, when breast fed, succumbed to infantile beri-beri. Paræsthesia and tingling were present over the trunk and extremities, and occasionally œdema. The last two months of pregnancy were the most usual time for the occurrence and in some cases the symptoms disappeared with parturition. In some the symptoms persisted for two or three months after labour and in the extreme grades of the disease, *i.e.*, those showing muscular wasting and foot drop, recovery took five months or more. No differences in diet were found between the sufferers and non-sufferers. Semi-polished rice, fish and vegetables formed the main part of the diet.

This author was inclined to the view that the condition is a toxæmia of pregnancy. True beri-beri cases seen in the Philippine General Hospital tended to be immune after one attack, but in the malady under discussion the symptoms often recurred in successive pregnancies. It is interesting to note that the neuritis is by far the most frequent in primiparæ, both in his series and ours. He also mentions the possibility of pressure on pelvic nerves as a possible causative factor.

What baffles us, while reading the report, is why a similar neuritic condition, if it is just a toxæmia of pregnancy or pressure on pelvic nerves, should not have been observed in other parts of the world, whereas in our search of the literature on this subject we can only find references to similar conditions in areas where beri-beri is present as well.

Acosta-Sison summarized his observations by saying that beri-beri does exist both in mothers and babies, but that all neuritic symptoms among parturients are not of beri-beri origin. One observation of his which tallies with ours is that mothers who have beri-beri, or rather polyneuritis, rear quite healthy babies. The point that strikes one in this observation is that beri-beri is possibly not a toxæmia, or at any rate the toxin is not inimical to the growth of the baby. Avitaminosis as the sole factor in the causation of beri-beri is not a tenable hypothesis, in the light of many investigations. Even if it is due to toxins, two factors are necessary for the manifestation of the symptoms of beri-beri—the 'predisposing' and the 'exciting', let us call them for want of better terminology.

Chopra and Acton (1925) in concluding their elaborate observations on beri-beri said that susceptibility played an important part when the amount of poison ingested was small. They instanced the small incidence of beri-beri in a jail population with a constant diet. Hypo-adrenalæmia in particular and hypo-thyroid to a lesser extent increase the susceptibility towards the poisonous bases which cause epidemic dropsy and beri-beri. They cited the colour of animals as markedly affecting the ease with which beri-beri could be produced, and pointed out that colour is associated with the endocrine mechanism. Autopsy of beri-beri cases often showed hypertrophy of the suprarenals. That there is deficient adrenalin in circulation and that an effort is made by the hypertrophy of the glands to make good the deficiency, seems to be fairly evident.

Does pregnancy bring about a condition of hypo-adrenalæmia or is there an exhaustion of adrenal activity immediately after labour which precipitates the symptoms of beri-beri when the other factor is already present.

Cannon (1929) has formed a very definite view regarding the ætiology of beri-beri, based on two years' observation in over 600 Chinese patients and 80 autopsies, helped by animal experiments. He says in conclusion, 'beri-beri is a syndrome of the orient confined to orientals chiefly males—seasonal in occurrence, prevalent during the wet season—partly infective—a rice disease—brought about by three factors (1) water-soluble vitamin B deficiency, (2) a bacterial infection closely resembling or identical with *B. asthenogenes* of Bernard (1919) and (3) an endocrine organ disturbance'.

Shiroki and Zakeshi (1929) claim that beri-beri is a syndrome caused either by lack of vitamin B or increased excitability of the sympathetic nervous system—a condition of neurasthenia sympathetica. By repeated electrical stimulation of the sympathetic nerves in the legs of rabbits, a condition resembling human beri-beri was produced. The incidence of beri-beri is

MALARIA DUE TO *P. vivax*

Introductory

DURING the last few years, the treatment of neural syphilis by the artificial induction of

(Continued from previous column)

correlated by these authors with climatic and meteorological conditions, age, sex, pregnancy and other factors that influence the sympathetic mechanism.

The unstable sympathetic system associated with pregnancy and labour and the concomitant upset of endocrine balance have, to our minds, a great deal to do with the appearance of symptoms of polyneuritis after parturition, in an area where the other contributory causes of beri-beri are present.

Conclusions

(1) Peripheral neuritis is not a commonly recognized complication of pregnancy nor of the puerperium.

(2) Peripheral neuritis is common in the puerperium in Vizagapatam, which is an endemic area of beri-beri.

(3) These cases differ in their clinical picture from those of true beri-beri.

(4) These cases are to be regarded as peripheral neuritis occurring in persons who are otherwise predisposed to beri-beri.

(5) Pregnancy—particularly in the later months—and the strain of labour seem to induce endocrine imbalance or other disturbance, and it is suggested that this may be the mechanism by which an attack of peripheral neuritis of this type is precipitated during the puerperium, in persons living in an endemic area.

Our thanks are due to Drs. G. Dinker Rao and P. Arunachalam for their valuable help and for the permission to utilize their case records.

malaria has offered a unique opportunity for studying the process of invasion of the blood by malarial parasites, and the early clinical manifestations of malaria. In this sphere, the work of James (1926 and 1926a) is outstanding. His findings are of such importance that they might be quoted fairly fully.

He found that *primary infections* by *P. vivax* produced usually the following manifestations:—

(1) An initial stage lasting from two to five days with sub-continuous, and later, remittent fever with no rigors, followed sometimes by an intermission of 24 or 48 hours.

(2) A developed stage which in 80 per cent of cases was characterized by quotidian (not tertian) inter-mittent fever with rigors, this stage often lasting more than 10 days.

(3) A terminal stage characterized by fever of tertian type.

He found that a second attack, produced by a new infection, showed a clinical picture quite different from the primary attack, the fever being tertian from the start. He found that relapses showed the same characteristics as the second attack, the fever being nearly always of true tertian type. He attributes the quotidian fever of the primary attack to the fact that the parasites do not all mature at the same time, several crops of parasites maturing at intervals and producing the sub-continuous fever of the initial stage. Later, two of the crops, each maturing on alternate days, became dominant, thus causing the quotidian fever of the developed stage; later still, one of these crops died out leaving only one main crop, resulting in the tertian fever of the terminal stage.

These findings of James were made in artificially-induced malaria in England. It is important to discover if the same findings are true of naturally-acquired malaria in countries such as India. This was one of the main objects of the work reported in this paper.

A second object was to study the phenomenon of spontaneous arrest, and to find out with what frequency it occurred and whether it was permanent. The importance of this branch of study was obvious. In testing the therapeutic efficacy of anti-malarial drugs, the recovery rate and subsequent relapse rate are usually recorded, but it is often insufficiently realized that there is a considerable spontaneous recovery rate, and that this recovery is not always followed by a relapse, even in the absence of any further malarial treatment whatsoever.

kept, and blood examination performed four times daily. This four-hourly blood examination included a total parasite count by the method of Sinton (1924), and a differential parasite count, the parasites being classified as rings, trophozoites, schizonts and gametocytes.

The numerical studies made will be discussed fully in another paper. In the present paper we deal only with the clinical findings and the main findings of blood examinations.

Thirty-seven cases of malaria due to *P. vivax* were chosen as having previously shown no manifestations of malaria since admission to the institution, which was at least one year previously and in most cases considerably longer. Three cases of relapse were investigated for comparison. All the forty patients were kept without quinine until the character of the fever had been investigated. At this stage 24 patients were given quinine and were not investigated further. The remaining sixteen however were kept without quinine for longer periods in order to observe the phenomenon of spontaneous arrest.

It should be clearly understood that most of our 'fresh' cases were probably not primary infections. The patients lived in areas where malaria was endemic, but not highly endemic, and they had probably had malaria before. This probably had an influence on our findings.

Clinical findings

(a) *Onset*.—The first point to notice is that in all these cases the first symptoms were headache, pains in the limbs and a definite rigor followed by fever. In three cases only, vomiting occurred. There were no really serious symptoms, such as collapse or coma.

Manson-Bahr (1921) states, of malaria in general, that 'two-thirds of the rigors come off between midnight and midday', yet, strange to say, the typical benign tertian temperature chart he reproduces shows rigors between 4 and 5 p.m. and his charts of quartan and malignant tertian also show the highest temperatures after midday. His statement is certainly not verified in the present series of cases, in fact of 71 rigors due to *P. vivax*, 66 occurred between midday and midnight. In these cases rigors were observed on 71 occasions, and the times were as follows:—In 31 cases the rigor occurred between 12 midday and 3 p.m., in 25 cases between 3 p.m. and 6 p.m., and in 7 cases between 6 p.m. and 9 p.m., in 1 case at 3 a.m., and in 4 cases between 9 a.m. and 12 noon. The matter of the time of rigors is discussed more fully later.

(b) *Development of the fever*.—Nearly all the patients came for examination within an hour or two of the first rigor, and the temperatures recorded varied from 101° to 104°F., with an average of 102.8°F. In nearly every case the temperature fell to below normal within six or seven hours, and remained normal or sub-normal

until the next rigor, which usually occurred about 24 hours after the first. Sometimes the second rigor and fever were less severe and sometimes more severe than the first, but in no case, even after several rigors, did any symptoms develop which suggested that the patient's life was in danger. There were pyrexia, headache, pain in the limbs and occasionally vomiting. In between the rigors the patients felt fairly well but weak.

(c) *The relation between blood findings and the type of fever.*—Early in this investigation it became obvious that there was an intimate connection between the blood findings and the type of fever. All the fevers in malaria due to *P. vivax* were found to be intermittent but some patients showed a rigor every day and some every other day. Blood examination

infection was on the decline and would no doubt have been arrested in time. In the other 11 cases the parasites disappeared without any treatment, but two of these patients had a slight relapse which again cleared up without quinine. (The records of a typical case are reproduced below.) In these 11 cases showing spontaneous arrest, the duration of symptoms after the first rigor varied from 3 to 14 days with an average of 6 days. Five other patients were kept for 8, 7, 5, 4 and 3 days without quinine and still showed moderate infection. One patient showed increasing infection for four days.

Relapse.—All the 40 cases were kept under close observation for several months after arrest of the fever; temperatures were taken at 4 p.m. each day for two or three weeks, and then two

CHART I

fresh infection with *P. vivax*.
quotidian intermittent fever.

Patient G. B.

showed that those patients with daily rigors always showed two distinct main crops of parasites in the blood, with a difference in growth of the two crops corresponding to a difference in age of about 24 hours. For example, patient G. B. on the first examination at 12 noon showed part-grown trophozoites, results of schizogony completed the previous evening, and also some full-grown trophozoites and early schizonts due to mature in a few hours, which they did at 4 p.m. that day causing another rigor less than 24 hours after the first rigor. Careful examination showed that in every case with daily rigors the finding of two main crops of parasites was made in the blood. In those cases (10 in number) showing only one main crop of parasites, rigors every other day were observed.

(d) *Spontaneous arrest.*—In 16 cases of malaria due to *P. vivax*, quinine was withheld for varying periods in order to observe whether spontaneous arrest would occur, but in five of these cases quinine was given later, not because the patients were in real danger, but because the daily rigors had such a weakening and depressing effect. In almost every case the

Patient P.

or three times a week, the blood examinations being made frequently by the thick film method.

Of 29 treated cases, none showed relapse during the ensuing six months. (The treatment given consisted of cinchona febrifuge, gr. 24 a day for one week, gr. 12 a day for the second week.)

Of 11 cases showing spontaneous arrest, in two there was a relapse, in each case slight and subsiding spontaneously in a few days. In one of these two cases a second relapse occurred; it again subsided spontaneously, and no further relapse occurred during the ensuing few months. All cases of relapse showed one single crop of parasites in the blood and the typical tertian fever of the textbooks.

One patient, about three weeks after spontaneous arrest of malaria, showed, at daily routine blood examination, a recurrence of parasites in the blood. Parasites were found for two days in small numbers, the parasite count not rising higher than 50 per cubic millimetre. The patient had no fever and felt quite well. The parasites disappeared spontaneously.

On the 26th September at 8 a.m. only one trophozoite was found in a thick film. Subsequently repeated daily examination showed no parasites till 8th October when a relapse occurred which also cleared up spontaneously. The patient was examined weekly for several months but showed no parasites or fever.

Discussion

We are now in a position to discuss the findings of Manson-Bahr and James, quoted above, and to compare them with the present findings.

The time of the rigor.—The difference between these findings and the dictum of Manson-Bahr (1921) concerning the times of rigors are very striking, and there must be some explanation. Manson-Bahr does not state in what type of patient or in what country the observations he records were made. In India in both European and Indian patients the rigors seem to occur most frequently between 2 and 4 o'clock in the afternoon. Lieut.-Col. Knowles informs me that he personally while in India has had malaria due to *P. vivax* with several relapses and invariably the rigors have occurred between 2 and 3 p.m., and that this personal observation has been verified in nearly all the malaria cases he has dealt with.

As far as we have been able to trace, the only work done on the factors governing the time of the rigor is that done in avian malaria by Boyd (1929). By keeping infected birds in the dark during the day and in bright light during the night, he found that within three days the time of the rigors shifted from the evening to the corresponding morning hours. This is a very interesting finding, but it is not clear whether the change was due to the change in the hours of light, or to associated changes in the hours of feeding, exercise and sleep. We would suggest that the time of rigor may be

affected by all these factors, light, food, exercise and sleep, and that in some countries in seasons when the sun rises early and where food and exercise are taken early, the rigors occur early in the day. In India the sun rises comparatively late, and only very light food is taken early in the day, the first real meal being taken at about midday. This we think may help to cause the later rigors. Quite possibly the time of the rigor may be affected by the amount of blood sugar which tends to rise after a meal and after exercise. The work of Hegner and MacDougall (1926) and MacDougall (1927) has shown that the growth of malaria parasites is favoured by an increase and partly inhibited by a decrease in the blood sugar. This fact may be of importance in governing the time of the rigors. These are only suggestions and they need investigation.

Initial stage.—James reports from 2 to 5 days of gradually increasing fever with rigors. In the present series of cases this initial stage was either so slight as to evade detection, or else absent. James says that the initial fever is absent in people who have had malaria before. The present series of cases were all fresh, but not primary, infections. Probably most of them had had malaria before, perhaps several years before. This fact may explain the absence of the initial stage.

Developed and terminal stages.—James reports in from 80 to 90 per cent of cases a developed stage of daily intermittent fever with rigors,

lasting 10 days or more. Our findings in the present series of cases are the same as those of James, namely that infection by *P. vivax* usually produces daily rigors. The percentage in the present series is 72 showing daily rigors. Regarding the duration of the developed stage our present findings give little evidence, for no cases have continued under observation and passed from the developed stage of daily rigors to the terminal stage of tertian rigors, as they have either cleared up spontaneously or else been given quinine before this could occur.

Relapse.—James says that relapsed cases show tertian fever from the start. Three of our patients, who have up to the present had a relapse, showed with the relapse a tertian fever, while their primary attack showed daily rigors. Our experience of malaria and relapse during several years supports James' findings.

Re-infection.—James states that re-infection produces tertian fever. Most cases of the present series must almost certainly have had malaria before, yet most of them show daily rigors. In this respect the present findings do not support James. A possible reason for this is that, in James' cases, re-infection occurred within five months of the first infection and while there was still some immunity, but in the present series the patients have been free from malaria for at least a year and usually much longer. We suggest that James' statement may be true only for a limited period, and that after that period has passed daily fever with rigors is commonly seen in re-infection.

Spontaneous arrest.—Every case in which quinine was withheld for a sufficient length of time underwent spontaneous arrest. Our opinion is that in Hyderabad most cases of malaria due to fresh infection of *P. vivax* undergo spontaneous arrest within two weeks. Relapse may occur but not by any means in all cases. Fresh cases of malaria are very common in the rainy season and shortly afterwards. Chronic malaria is much less commonly seen. Among about 2,500 patients who have passed through this institution (a leprosy hospital) in eight years, enlarged malarial spleens have been seen in about a dozen cases, whereas between fifty and a hundred fresh cases of malaria are seen every year. This is in marked contrast to the findings of most workers on malaria due to *P. vivax*. Knowles states, 'Almost all cases of malaria encountered in hospital in Bengal are of the endemic, chronic or residual type'. Even making allowance for the difference between hospital and institutional work, we think that chronic malaria is much less common in the rural areas of Hyderabad than one would expect. There are practically no data concerning spleen rates, etc., in rural areas of Hyderabad, but the writer's experience is that the spleen rates are extraordinarily low when the high incidence of malaria in the rainy season is considered. In the city of Hyderabad, spleen rates

in children have been recorded and it is found that they vary tremendously in different parts. Some areas show 80 per cent and other adjacent areas only 3 per cent. There seem to be marked differences between city and rural areas, and also between various parts of the city. The whole subject is one needing careful investigation and it cannot be dealt with here.

On the whole then our clinical findings support those of James but there are certain differences which may be summarized as follows:—

(1) The initial stage of James is either so slight as to be undetected, or absent.

(2) Re-infection, if it occurs a long time after the previous infection, usually produces daily rigors and fever, and not tertian rigors and fever.

(3) Most cases become spontaneously arrested before the 'terminal stage' of tertian fever.

The explanation for these differences probably lies in differences in the type of patient. James' patients with fresh infection were all cases in England where endemic malaria is practically non-existent, and they could have developed no immunity as the result of previous infection. The present cases were all patients in an area where malaria is endemic and they all probably have some immunity as the result of previous attacks. James' re-infected patients were all re-infected within five months of the initial attack. Our patients were mostly re-infected cases but the previous infection took place at least one year and probably several years before.

The important clinical finding of James, which the present findings support, is that infection by *P. vivax* usually produces at first an intermittent fever with daily rigors and not with tertian rigors as is described in most textbooks. The phenomenon of a daily rigor is explained by the finding that the parasites mature in two main crops with an interval of about 24 hours between them. It has long been known that patients with malaria due to *P. vivax* may show daily rigors, but this was regarded as exceptional, and in most textbooks it is attributed to 'double infection'. Exactly what is meant by 'double infection' is not clear. Some writers imply, but do not state definitely, that it is due to bites by infected mosquitoes on more than one occasion, the parasites maturing at different times. Others use the term 'double infection' with no explanation. The finding of James and our present findings show that the daily rigor is not the exception but the rule in fresh cases, and that it is caused by one infection only, the parasites maturing in two main crops.

The daily rigor has a most weakening effect on the patient. A patient who has had tertian fever for a week, even if it is severe, often walks about and feels fairly well in the intervals between the fever, but a patient who has had daily rigors for the same time is usually so weak and exhausted that he can do practically

nothing. The daily fever is much more than twice as exhausting as the tertian fever, for the patient has little interval between the rigors in which to recover his strength.

The present blood findings

James' findings are in general agreement with the present findings. The only difference is that we feel that a definite division into two crops of parasites is possible more frequently and at an earlier stage than James indicates.

In all forms of malaria, even in the classical benign tertian malaria, the parasites are never found exactly at the same stage of development. The rupture of mature schizonts is spread over several hours and the rigor occurs at the height and not at the beginning of this process. Thus, in a case of malaria due to *P. vivax* with tertian ague and only one crop of parasites, rings and mature schizonts are found together in the blood for several hours in varying proportions, from an hour or two before the rigor to an hour or two after the rigor. When two crops of parasites are present the blood picture is more complicated, and rings, early trophozoites, half-grown trophozoites and schizonts are often seen together, but it is usually possible to place 90 per cent of the parasites in one or the other main crop. The other 10 per cent may be doubtful but this is only to be expected and does not materially affect the general finding that the parasites are in two main crops.

To demonstrate this matter clearly, a relapsed case showing a typical tertian fever due to *P. vivax* was investigated, very careful differential (asexual) parasite counts being done every four hours, and the parasites classified as follows: rings and early trophozoites—T1, half-grown trophozoites—T2, full-grown trophozoites—T3, immature schizonts—S1, and mature schizonts—S2. The results for two days were as follows:—

	T1	T2	T3	S1	S2
12 noon	..	95%	5%
4 p.m.	..	31%	69%
8 p.m.	..	3%	97%
8 a.m.	29%	62%	9%
10-30 a.m. (rigor 11 a.m.)	14%	81%	5%
12 noon	..	25%	..	70%	5%
4 p.m.	..	75%	25%

Here is one main crop of parasites but there are minor differences in development. At each examination parasites in at least two stages are seen but the difference in development is slight and they all obviously belong to the same main crop. Rings are found only about the time of the rigor and there is apparently no schizogony going on at other times. If we consider the two counts taken at 12 noon (the rigor occurred at 11 a.m. the second day) we find that all forms of parasites are present on one or other occasion. Now, if in one patient we have two main crops of parasites one maturing each

twenty-four hours, and if we make a blood examination one hour after the rigor, we should expect to get a blood finding similar to that obtained by adding together the blood examination results obtained at 12 noon on successive days in the above patient who showed only one crop of parasites. This is what we actually do find. Below is given a typical differential count actually made one hour after the first rigor in a patient showing two main crops of parasites, compared with a composite count made by adding the noon counts on two successive days of the patient showing a single crop:—

	T1	T2	T3	S1	S2
Actual count	27%	59%	3%	9%	2%
Composite count	12.5%	47.5%	2.5%	35%	2.5%

This shows that the finding of some parasites at all stages does not necessarily prevent a division into two main crops. The one crop here is represented by part-grown and full-grown trophozoites (T2 and T3) and the other crop by schizonts immature and mature, and early ring trophozoites (S1, S2, and T1).

The strongest proof that, in such cases as the one just quoted, the parasites are in two main crops is the fact that the early ring form of trophozoite is found, as a rule, only for certain limited periods, namely, for a short time before the rigor till two or three hours after the rigor. The rigors occur every day, and are caused by the completion of schizogony in one of the two crops of parasites.

During the present investigation, when a case of malaria came for examination after the first rigor, we found it possible in nearly every case from the study of a single blood film to predict the form the fever would take (whether quotidian or tertian), and if the time of the taking of the blood film was known, we could make a fairly accurate prediction of the time of the next rigor. The correspondence between blood findings and the type of fever was most striking, and was one of the outstanding facts demonstrated in the present enquiry.

Two main crops of parasites with quotidian fever were observed in 27 of 37 cases of malaria due to fresh infection by *P. vivax*. In one case the crops were not apparent at the first but only became apparent at the second examination.

MALARIA DUE TO *P. falciparum*

It was found impossible to carry out a similar thorough investigation of the fever produced by fresh infections of *P. falciparum*. The severe nature of the fever made the withholding of treatment for more than a short time a dangerous and unjustifiable procedure. Twenty-one cases of malaria due to *P. falciparum* were observed, and in eight of them quinine was withheld for periods varying from four to forty-eight hours from the time of making the diagnosis. The following is a summary of the observations made.

Clinical findings

The onset.—The onset was not nearly as sudden as in *P. vivax* infections. In very few of the patients was there a definite rigor with shivering. Usually there was a sensation of cold, headache and pains in the limbs. The symptoms increased until in most cases there was vomiting and some degree of collapse. The time of the onset of these symptoms was usually between 2 and 6 p.m. The temperature taken shortly after the onset varied from 101° to 105° with an average of 103.4°F.

The development of the fever.—Shortly after the onset the fever was high and remained high for several hours that evening. The next morning the fever in most cases was less, but the temperature was practically never normal. In most cases the temperature rose again about midday or shortly after, with a recurrence of the severe symptoms described above. In other cases the fever and other symptoms remained

CHART III

Fresh infection with *P. falciparum*.
Quotidian remittent fever.

Patient I. B.

slight during the second day and severe symptoms did not show themselves till the third day. One case took a hæmorrhagic form with petechial hæmorrhages in the skin, hæmaturia (bright-red blood), and bleeding from the bowel.

All cases after 48 hours (or before if necessary) were given quinine and had an uninterrupted recovery. All cases observed for a sufficient period showed a remittent, not an intermittent, fever. Four cases showed a tertian periodicity and four cases showed a quotidian

periodicity. One case showed continued high fever for 24 hours with no remission before quinine was given. The remaining 12 cases were given quinine before the periodicity became apparent.

Blood findings

The only form of the parasites seen in the peripheral blood in fresh cases was the early trophozoite, usually in its ring form, but the marginal forms were also common in the heavier infections. The number of parasites was always highest after the high fever and fell markedly when the temperature fell, but in the periods of remission of fever the only form seen was still the young trophozoite. There are three reasons for this. Firstly, *P. falciparum* retains the ring form for a long period, according to Thomson and Robertson (1929) as long as 24 hours in some cases. Secondly, all parasites disappear to the internal organs after about 24 hours growth. Thirdly, there appears to be

CHART IV

Fresh infection with *P. falciparum*.
Tertian remittent fever.

Patient E. G.

some schizogony going on continually, small numbers of early ring forms appearing in the peripheral blood every few hours. In addition to this slight amount of continued schizogony all cases showed periods of heavy schizogony. In some cases these occurred every 24 hours and in others every 48 hours. Thus the parasite counts were apparently made up of numerous small groups maturing at any time and either one or two main crops maturing at mid-day, or shortly after. The parasites belonging to the same main crop did not mature simultaneously. This process was spread over several hours.

The relation between the blood finding and the type of fever.—All cases observed showed a remittent, not an intermittent, fever, but some showed a quotidian periodicity and some a tertian periodicity. A study of the blood findings

helps to explain this. Schizogony was going on all the time to a mild degree, hence the temperature did not return to normal and the fever was remittent. The differing periodicity depended on whether there was one main crop, or two main crops with a difference of 24 hours in their development. Those patients with only one main crop showed a tertian periodicity. The fact that the maturing of the main crops was spread over several hours with a gradual, not a sudden, increase in the parasite count probably accounts for the fact that there was a gradual and not a sudden rise of temperature.

Summary

(a) Malaria due to *P. vivax*.

A study is made of thirty-seven cases of malaria due to fresh (but probably not primary) infection with *P. vivax*. Twenty-seven of them showed a quotidian intermittent fever. The rigors occurred usually after mid-day. Relapsed cases showed a tertian intermittent fever. The quotidian fever in fresh infections is found to be due to the parasites maturing in two main crops on alternate days. Most of the findings of James (1926) in experimentally-induced malaria are verified in this series of cases of naturally-acquired malaria. Eleven cases kept entirely without quinine showed spontaneous arrest of fever within two weeks, and in only two of these cases was there a relapse; these relapses subsided spontaneously.

(b) Malaria due to *P. falciparum*.

Twenty-one cases of fresh (but probably not primary) infection with *P. falciparum* were observed. In eight cases quinine was withheld for a time. Four of these cases showed a quotidian remittent fever, and four showed a tertian remittent fever. The fever was not intermittent because there was some sporulation of the parasites occurring all the time, but in addition there was either one or two main crops of parasites sporulating about midday, causing either a tertian or a quotidian periodicity.

My thanks are due to Dr. E. B. Christian, without whose very valuable assistance this work could not have been done.

CONJUNCTIVITIS PRODUCED BY A GROUND BEETLE

By R. N. CHOPRA, M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

School of Tropical Medicine and Hygiene, Calcutta

ONE evening in Calcutta about the middle of October soon after dusk when the writer was sitting in his car, which was stationary at the time, he saw a small insect flying towards him. Before he realized what was happening the insect flew straight into the lower lid of his right eye. The sensation for the time being was as if a red-hot charcoal had been put in the eyelid and for about one minute the pain was excruciating. The insect was removed from the eye by Dr. S. L. Hora of the Zoological Survey of India who very kindly took it for identification. After removal of the insect the pain and lachrymation continued, the eye became very red and congested, and the eyelids swelled up. On returning home, the writer washed out the eye with boric lotion, but the pain and watering continued throughout the night.

Next morning the eyelids were more swollen and congested, and there was a good deal of stringy muco-purulent discharge. The eye was examined by the resident surgeon of the eye hospital who found the conjunctiva of both lids inflamed but no injury to the cornea. The lower lid was particularly red and inflamed, and on closer examination two small wounds could be clearly seen near each other where the jaws of the insect had dug into the conjunctival tissue. The conjunctival sacs of both lids were irrigated with warm saline and a drop of 5 per cent protargol was put in. This treatment had to be continued for 4 days and after that the eye became normal.

On examination, the insect was found to be a ground beetle of the genus *Clivina*, and so far as it could be ascertained from a small, crushed specimen, it seemed to belong to *C. helferi* Putz; but, as it was not possible to examine all the characters of the specimen under report, the specific determination is given here with considerable reserve.

The species of *Clivina* live in moist places and commonly emerge in the evening. The genus belongs to the family *Carabidae* or 'Ground beetles'. Some of these insects

possess glands at the anal extremity from which they are able to discharge a fluid which volatilizes on contact with the air, and which possesses highly caustic properties'. When handled these beetles give out an odour like iodoform.

These beetles breed and live in unclean places and, apart from the irritant substances produced by glands in their body, they carry infective germs with them.

H. E. Andrews in his treatment of the *Carabidae* in the *Fauna of British India* series (*Carabidae*, Vol. I, London, 1929) remarks that, as a means of defence, the beetles of the group *Brachinini* and of the genus *Omphra* possess glands at the anal extremity from which a highly caustic fluid is discharged on irritation or in face of danger. 'This emission is not only

visible as a kind of smoke, but is apparently audible also, and no doubt it enables the insect to seek shelter whilst its enemy is recovering from the effects of the discharge'. The members of the genus *Clivina*, to which reference is made above, belong to the group *Scaritini* and to the sub-group *Clivinides*. So far as I am aware, the beetles of this group have not been accredited with the possession of pungent, caustic secretion. The above note, therefore, adds to our knowledge of the bionomics of the *Clivina* beetles.

I am very greatly indebted to Dr. S. L. Hora of the Zoological Survey of India for his co-operation and help. The specimen is preserved in the collection of the Zoological Survey of India, Indian Museum, Calcutta.

A Mirror of Hospital Practice

A CASE OF BILATERAL MACULAR DISEASE IN A CHILD

By S. N. MITTER, B.Sc., M.B., B.S., D.O.M.S. (Lond.)
Second Medical Officer, Shroff Charity Eye Hospital
Delhi

THE macula lutea is structurally as well as functionally a specialized portion of the retina, its nutrition differing to a considerable extent from other portions. We therefore meet with lesions which are practically limited to the macula. These lesions are usually bilateral, and the commonest types are—

- (a) Senile degenerative conditions of uncertain ætiology;
- (b) Lesions occurring after acute fevers, e.g., influenza or typhoid; these are inflammatory conditions almost certainly due to toxæmia, and hence capable of improvement if treated promptly.

This second condition is seen most commonly in children, and Hughes (1931) has described some cases which he considers to be due to measles. In his cases visual acuity was low and could not be improved. He contends that it is likely that other infectious diseases may produce bilateral macular disease in children. In my opinion this is true and I consider that after every acute illness in children the maculae should be very carefully examined for any early inflammatory lesion, for slight disturbances of vision are usually not noted by the children or are ignored by the parents, and it is only by early treatment that improvement can be produced. I have recently examined a boy whose visual acuity had fallen markedly after an attack of typhoid, and whose maculae showed gross pigmentary changes. Vision could not be improved very much, and I believe that this case was similar to those described by Hughes.

The following case suggests that factors other than acute fevers may possibly be responsible for producing bilateral macular disease.

D. S., aged 9 years, was brought to me by his father, who said that the boy first complained of dimness of vision about twenty days previously but this was ignored by the parents. Three days before they came to me the father saw the boy stumbling and obviously walking with difficulty. On examination by me it was seen that vision had been reduced in the right eye to 'fingers' at 10 feet, and in the left to 'fingers' at 8 feet. Pupil reactions and tension were normal; media were clear and there was a total hyperopia of three dioptres; vision, however, did not improve with glasses. The maculae of both eyes were dark and oedematous and showed some pigmentary disturbance; in the left, the oedema had spread almost up to the papilla. The pigment was very small in amount and seemed to be coarse: neither hæmorrhage nor any exudate could be seen anywhere in the fundi. Blood vessels were not affected and the rest of both fundi seemed to be normal. The urine contained an appreciable quantity of phosphates.

Cure was rapid in this case, the patient recovering to '6/9 partial' in each eye in three weeks. The retinal oedema had entirely disappeared and the maculae presented a more or less normal appearance; some very fine pigment was, however, still left, and further improvement of vision was probably not possible owing to this. Besides local treatment with atropin, dionin and a few subconjunctival injections of normal saline, the patient had iodides and full doses of sodium salicylates internally. He was later put on Sajodin and thyroid and allowed to return home. Ten months after this he was examined again: the macular condition remained unchanged, and he was attending school normally.

This symmetrical inflammatory lesion in both maculae suggested a general cause and led to a search for any focus of infection in this apparently healthy child. No history of any acute or infectious disease could be elicited; there was no oral sepsis nor sinusitis, and the Wassermann reaction was completely negative. The skin was generally dry, and on the abdomen, arms and legs it was scaly. The father said that the child was born with this condition

A CASE OF ADDISON'S DISEASE ?

By GANESH CH. SARKAR, M.B.

Teacher of Medicine, Ronaldshay Medical School
Burdwan

THE patient, a Hindu male, aged 38, a labourer, was admitted to the medical ward of the Fraser Hospital, Burdwan, on 3rd August, 1933, with rapidly-developing pigmentation of the body particularly on the extremities, puffiness about the ankles, asthenia and inability to carry on his ordinary work, and gastro-intestinal disturbances. The symptoms were of three months duration. Family and personal histories showed little of interest. Except for occasional short spells of fever he was never ill seriously. He had syphilis about four years before. For three months his relatives had

(Continued from previous page)

which became worse in the winter and improved in summer, and that temporary benefit resulted from massage with oil. This congenital ichthyosis has been observed for three generations in the family of the patient's mother, and strangely enough had affected the male members only. I examined the fundi of the patient's brothers and sisters (five in all), and found them to be normal in every respect. Although one of the affected brothers was mentally weak, so much so that he had to discontinue his schooling; the patient himself was a brilliant boy.

Whether congenital ichthyosis can be responsible for a bilateral inflammatory disease of the macula, I am not certain; but in this case this seemed to be the only factor that was present. Porter (1926) has shown that 70 per cent of children affected with congenital ichthyosis show a subnormal basal metabolic rate which suggests hypothyroidism. In this case it is possible that though there was no evidence of a definite thyroid insufficiency, this subnormal or faulty metabolism had resulted in some form of mild toxæmia which might have affected the maculae. Metabolic toxins are known to affect markedly the walls of the capillaries, and it is suggested that an increased passage of colloids through the capillary walls may lead not only to a loss of the 'pristine brilliancy' of the fundus oculi but also to definite œdema in some cases. The importance of inborn errors of metabolism in causing ocular disturbances is discussed in a recent paper by Ramsay (1933). He ends with the very pregnant suggestion that such errors may be responsible even for the toxic amblyopias, and he therefore recommends a systematic examination of blood sugar in such cases.

noticed the pigmentation, but he came to hospital mainly on account of the weakness, gastro-intestinal trouble, and swelling of the ankles.

He was somewhat thin and anæmic. A blackish pigmentation was noticeable all over, but was more marked on the face, lips, neck, extremities, serotum, and penis. The skin was dry but not shrivelled; there was slight œdema around the ankles. His appetite was perverted and anorexia was marked. He complained of nausea, felt mostly in the morning, while the bowels were irregular. His teeth were healthy and the buccal mucous membrane showed pigmented spots. The tongue showed pigmentation particularly at the sides, while the palate also showed the same type of pigmentation. The conjunctivæ were pearly white with black spots near the sclero-corneal junction. The blood pressure was low—80 mm. Hg. (systolic). The pulse was feeble, easily compressible and the rate was 66 per minute. The apex beat was not marked and on auscultation the heart sounds were weak. Secondary anæmia was present, blood examination showing red blood cells—42 millions, hæmoglobin—50 per cent. The total white count—6,000. The differential count was lymphocytes—26 per cent, polymorphs—64 per cent, large mononuclears—4 per cent, eosinophiles—6 per cent. The blood sugar was 0.081 per cent, and the Wassermann test was positive (5/10). Urine examination showed no abnormality; the spleen and liver were not palpable below the costal margin.

The weakness and pigmentation suggests pernicious anæmia, but the blood picture excludes it; other causes of pigmentation and gastric disturbance must be considered, such as arsenical poisoning, abdominal growths (e.g., gastric carcinoma), but there is no history of taking arsenic. Stool examination for occult blood showed nothing. As kala-azar is excluded by the absence of either enlarged spleen or liver a diagnosis of Addison's disease was made.

The treatment adopted was of the type employed by Rowntree, and consisted in frequent administration of adrenalin hypodermically (daily five minims) and of the extracts of whole gland by the mouth to the limit of tolerance (up to 10 grains three times a day). The avoidance of fatigue and worry was strictly enforced, and absolute rest in bed was maintained. An easily digestible diet was given, and as the blood sugar level was low, carbohydrates were given liberally. As syphilis was possibly the causal factor in the case, anti-syphilitic treatment as advised by Warthin was given. Potassium iodide was given, 10 grains three times a day, increasing the dose with the progress of the case. Arsenic was not given. The tuberculin treatment was not adopted as the case appeared to be mostly of specific origin.

The patient improved rapidly, the pigmentation became much fainter, while the weakness became less and the gastro-intestinal disturbances almost subsided. He could now easily move about, his appetite returned and he was not satisfied with the food supplied to him. He left hospital fifteen days after admission. Owing to domestic reasons he could stay no longer in hospital.

(Note.—We do not feel that we can accept the writer's diagnosis without some comment.

The symptoms certainly suggest adrenal dysfunction, but this occurs in many other conditions besides true Addison's disease. We do not think that this disease would have responded in so short a period as fifteen days to the treatment that was given; on the other hand potassium iodide will often increase adrenal function temporarily. The absence of enlargement of the spleen or liver does not by any means exclude kala-azar. In both kala-azar and hookworm disease there is adrenal dysfunction; certain other symptoms in this case suggest that ancylostomiasis might have been the cause of the disability.—EDITOR, I. M. G.)

A CASE OF GANGRENE COMPLICATING TYPHOID FEVER

By R. W. THOMAS, M.B., B.S. (Lond.), D.T.M. & H.
and

E. RILEY, M.B., Ch.B. (Vict.)
Baptist Mission Hospital, Palwal, S. Punjab

In view of the rarity of gangrene in typhoid fever, the following case appears worthy of publication:—

A Hindu male, aged 52, presented himself at the above hospital on 10th August, 1933, for treatment for his feet, from both of which all the toes were missing.

History.—Eleven months ago he had an attack of fever with headache, the fever being continuous and high for three weeks, then becoming intermittent for 10 days. During the period of high fever, he was semi-comatose. When the fever had been intermittent for a few days, the toes of both feet became quite cold and numb, and the following day both feet were greatly swollen to just above the ankles. Five days later a burning sensation was felt in the feet, and a fortnight later ulceration set in and the toes became very painful. All the toes sloughed off within three months.

At the same time that ulceration commenced in the toes, there was ulceration of the terminal phalanges of the right little finger and of the middle finger of the left hand. The patient took little notice of these and after three months he pulled off the necrosed parts and the fingers healed up.

The patient's previous history revealed nothing of note. He denied having had syphilis and there was no history of previous attacks of coldness and numbness of the extremities, nor of intermittent claudication. During the illness recorded above, he was not seen by any doctor.

Physical examination.—The patient was a well-built muscular man and appeared healthy. He walked with difficulty since all the toes of both feet were missing. There was a healing ulcerated line on each foot corresponding to the line of the metatarso-phalangeal joints. This was tender to touch owing to nerve exposure. The terminal phalanx of the little finger of the right hand was missing, and there was scarring and loss of tissue in the pulp of the terminal phalanx of the left middle finger. The feet and legs were not swollen and there was no varicosity of the superficial veins. There was no anæsthesia, but slight hyperæsthesia; and in the affected fingers slight loss of thermal sensibility was detected.

Arterial pulsation was everywhere good, and there was no atheromatous thickening of the arteries. In the left popliteal space, a cord-like thickening was palpable overlying the artery, possibly a thrombosed popliteal vein.

The blood pressure was 140 mm. Pupils were equal and reacted to light and accommodation. The left lens was cataractous. Knee-jerks were elicited. There

was no enlargement of the ulnar or external popliteal nerves; and no rash or skin lesion. The chest and abdomen were clear.

Urine.—Specific gravity—1010, acid, no albumin or sugar. Phosphates +. The Wassermann test was not done.

This appears to be a case of gangrene of the extremities in the course of some febrile disease, probably enteric fever. In considering the differential diagnosis, we may from the history and physical signs rule out such causes of gangrene as arteriosclerosis, diabetes, thromboangiitis obliterans, syringomyelia and syphilis.

Leprosy has to be considered, but there are no evidences of it in the form of anæsthesia, nerve-thickening, or skin rash, and the sudden onset in all four limbs helps to rule it out.

Raynaud's disease is a possible diagnosis, but the sudden onset in the course of a febrile disease with no previous history suggesting this disease is against it. It is unusual, moreover, for the gangrene in Raynaud's disease to lead to more than superficial necrosis, though Choyce (*System of Surgery*, Vol. I, p. 209) records a case of gangrene in all four extremities with a sudden onset, which he attributes to Raynaud's disease. There was no evidence of ergotism.

It is difficult to say what the mechanism of the production of gangrene in this case may have been. The hard cord palpable in the left popliteal space suggests that venous thrombosis may have occurred, but the lack of superficial varicosity suggests that there must have been some other factor at work, possibly arterial spasm of the type seen in Raynaud's disease, due in this instance to toxæmia and debility.

TETANUS CURED BY MAGNESIUM SULPHATE

By R. K. BOSE, L.M.S. (Cal.)

Medical Officer, Dumraon Raj Hospital, Dumraon

THE patient—a Hindu male child aged 4, admitted on 31st October, 1933, for treatment of an ulcer on his head.

On examination the following signs were observed; these had apparently escaped the notice of his parents. He had difficulty in swallowing, could only partially open his mouth and his eyes were partly closed, the lower extremities were stiff and abdomen rigid; these signs were detected accidentally as the boy was brought here for the cure of the ulcer on his head.

31st October, 1933. Treatment:—One c.cm. magnesium sulphate solution (25 per cent) was injected subcutaneously morning and evening, and chloral hydrate gr. v, potassium bromide gr. v in aqua chloroformi, half an ounce, given twice daily.

3rd November, 1933. From this day 2 c.cm. of magnesium sulphate solution was injected twice daily.

9th November, 1933. The boy had distinctly improved, he could open his mouth widely, eat his food easily, and could walk one or two steps, but still had some stiffness of his legs.

The injections and chloral mixture were continued up to this date. From this time he continued to improve steadily and he was discharged cured four days later.

(Note: It seems doubtful if this degree of spasticity justifies the diagnosis of tetanus. Ep., I. M. G.)

Indian Medical Gazette

JANUARY

FIFTY YEARS AGO

During the last year we have printed, month by month, extracts from the corresponding numbers of this journal of the year 1883. The reading of this old volume, whose leaves after half a century of Bengal's climate are so friable that it is difficult to turn them without tearing them, has both a stimulating and a sobering effect—stimulating, because one sees not only that great strides have been made in the theory of medical science during the last fifty years, but that these theoretical advances have been translated into practical achievements and that the health, in controlled communities at any rate, the Indian and British Armies and the jail populations for example, has undergone a revolutionary change—sobering, because we realize that many of the vistas which then appeared to be opening up have proved to be nothing but mirages, that some of the 'advances' of the intervening years have been made around a circle, so that to-day we find ourselves coming to conclusions already arrived at by our predecessors of fifty years ago, and finally that in a few instances practices that even then were not considered satisfactory have remained unchanged throughout this period.

In 1883 the 'germ theory' of disease was in its early infancy, during the previous year Koch had announced his discovery of the tubercle bacillus, and the discovery of the causative organisms of all diseases was thought by many to be only a matter of time. It had been assumed for some time that typhoid and cholera were both caused by 'germs', that these germs were excreted in the stools of patients, and that they were able to multiply outside the body. Eberth had isolated the causative organism of the former disease three years before, and actually during this year Koch, at the head of a German commission, had come out to study cholera in its home in Bengal, where in the same year he first isolated the vibrio. But in anticipation of these discoveries preventive measures were already being based on the germ theory of the causation of these diseases. There were at this time many sceptics who refused to believe in the germ theory at all, but, as the editor of the *Gazette* at that time pointed out, their scepticism was seldom based on scientific research, more often on intuition and arithmetic; on the other hand there were those who, whilst admitting that germs caused disease, refused to accept the germ theory as the whole truth. In the presence of the rising tide of enthusiasm for this theory the words of these more cautious advisers were at first ignored and

later forgotten, but to-day, when the bacteriological factor is being viewed in its proper perspective and is being considered, not as the only factor, but, with immunity, diet, environment and others as one of the many factors that go to form the epidemiology of the disease, anyone who will take the trouble to look up the old journals and read the criticisms of the more moderate elements in the profession in those days will be struck by the shrewdness and wisdom of some of their observations.

We have mentioned above that Koch came to India during this year to study cholera; earlier in the year a commission was also sent out from France at the suggestion of Pasteur; Dr. Roux, who died only a few months ago, was a member of this commission. This interest of foreign scientists in cholera in India shows that it was fully appreciated even then that India was the home of the disease, and it was evidently thought that the best method of attacking it was to beard it in its lair; this policy was however not a success, as in fifty years the cholera position in Bengal has undergone little change, but other and effective methods have been adopted by foreign countries to prevent the extension of the disease into their territories, so that in Europe to-day cholera is almost unknown.

In the January (1883) number a writer, discussing the recent advances in bacteriology, points out the necessity for an exact knowledge of the nature of the 'microphytes' that cause different zymotic diseases, so that action against them can be specific and not empirical; he goes on to say that, whatever other action is taken, it must be accompanied by the remedying of sanitary shortcomings. The zymotic diseases with which they were most concerned were enteric and cholera; despite our increased knowledge of the nature of the causative organism of these diseases and despite the undoubted success of prophylactic inoculation, it might well be claimed to-day that wherever in the world lasting improvement in the incidence of these diseases has been achieved, this has been brought about mainly by sanitary reform in its most restricted sense. In the next number the views of von Pettenkofer, who was obviously not a whole-hearted supporter of the germ theory, are discussed; he claims that certain local and seasonal conditions are necessary for the effective action of the cholera germ, whether it be an essentially virulent organism or an innocent one that has acquired virulent properties by existence under special conditions. His opinions are particularly interesting in view of the recent epidemiological work on cholera, and of the bacteriophage work of Pasricha and others in which, by the action of bacteriophage, changes in the agglutinability—and possibly in the virulence—of vibrios has been effected.

The discussion in the March number on enteric fever does however demonstrate a very

definite advance in our knowledge since that date. The writer is puzzled by the fact that in England enteric is definitely an epidemic disease, that a community can drink sewage-contaminated water for some time with impunity, and that it is only when a case of enteric is imported that an epidemic occurs, whereas in India the disease appears to arise *de novo*, 'where no personal communication has arisen with anyone suffering from enteric fever, (and) no sanitary defects are discoverable'. To-day we know that an individual may remain a carrier for a long time, that the indigenous inhabitants of India are not immune from the disease but that it is common amongst them, and that the sanitary standards of fifty years ago were not sufficiently high to exclude the possibility of the introduction of infection; with this knowledge the facts that puzzled the writer of 1883 seem to us to be the natural result of existent conditions.

In the April number there is a warning from the surgeon-general in Bengal that an epidemic of cholera was about to take flight from Bengal up to the Gangetic plain; this prophecy proved true, just as those of a similarly highly placed official that have appeared in recent years in this journal have done; and in the October number yet another surgeon-general's description of conditions suggesting partial failure of the monsoon, which he says are those that are likely to lead to a cholera epidemic, is very familiar to the present-day readers of this journal.

The paucity of references to malaria in this volume cannot be taken as an indication that the disease was not an important one, but it was probably due to the fact that malaria was not generally recognized as a zymotic disease, being looked upon as the standard fever of tropical countries about which little could be done except in the way of treatment. The subject had not then received the stimulus that was given to it a few years later when Laveran's discovery became more widely known and its significance appreciated, nor when some fourteen years later Ross made his classical contribution to the science of malariology. However, the subject was not entirely neglected and one gathers from the December number that the theory, revived by a recent director of public health in this province, that the malarious state of many districts in Bengal was brought about by the interference with natural drainage by road and railway embankments, was even in those days an old one, and was considered important enough to be the subject of a commission.

During fifty years the quinine position appears to have undergone very little change. The reports from the government cinchona plantations bear a striking resemblance to those of the present day, except that a greater proportion of cinchona febrifuge was manufactured

then; the price was Rs. 8-8-0 a pound, almost exactly the same as it is to-day. Since this day cinchona febrifuge has gone in and out of fashion more than once. Recent references by the League of Nations Health Organization might lead the uninitiated to imagine that Quinetum, now replaced by a standardized preparation, Totaquina, was of comparatively recent origin, yet in April 1883 it was referred to as 'the well-known cinchona febrifuge'.

In the same number a reference is made to Manson's work on filariasis transmission, which was the forerunner of Ross' malaria work, and to the fact—well recognized then but apparently sometimes forgotten to-day—that the embryo is found in the blood more often in persons without any pathological lesions than in those with elephantiasis.

There are indications in the May number of the birth of the 'rheumatic-fever-in-the-tropics' controversy, which still rages; the writer in this number has a theory that malaria and rheumatic fever are the same diseases, showing different manifestations in tropical and in non-tropical countries. His argument cannot have been very convincing, even in those days, but we are reminded that no revolutionary advance has been made since then in our knowledge regarding the latter disease.

Koch's discovery of the tubercle bacillus gave rise to hopes which were sadly unfulfilled; the writer of the following words must have been bitterly disappointed as the years rolled by and his ideal germicide failed to materialize. 'The germ theory' he wrote, 'being once placed on a stable footing, treatment—preventive and curative—by germicides would become an imperative necessity, and the only questions remaining for solution would be—what are the most effective germicides for particular varieties of pathogenic organisms, and how they can be most effectively applied in the special circumstances of each disease'. He recorded some that had been tried without success in tuberculosis, the failure being due in his opinion to the fact that the bacillus was (most annoyingly) extravascular and therefore uninfluenced by germicides circulating in the blood. He concludes naïvely, 'This subject therefore may also be considered *sub-judice*'. And so it has remained for fifty years!

The discovery of the leprosy bacillus preceded that of the tubercle bacillus by three or four years; it is amusing to read in the December number that a Swedish doctor had succeeded in infecting animals with leprosy. Few years have passed since this date without a similar success being reported, but leprologists of the present day are loath to admit that experimental infection has ever really been produced.

A link with the present is provided in an article by Arthur Neve of the Mission Hospital, Kashmir, who is, we believe, the brother of Dr. E. F. Neve who is still in charge of this

well-known hospital. Neve writes on the subject of radical cure of hernia; he refers to many of the methods then in vogue as 'barbarous' and advocates Spanton's method; this consists in obliterating the inguinal canal by means of a screw which gives rise to an inflammatory reaction followed by cicatrization. One wonders what the other *really* barbarous method must have been like! In justice to the times, it is only fair to say that this writer does not escape criticism; a polemic discussion followed in which Dr. Neve neatly turned the tables on his opponents by admitting that they had the advantage over him in that they were so often able to demonstrate the results of their operations in the post-mortem room. Other surgical references are to lithotomy and lithotrity, so that it is evident that the controversy regarding the respective merits of these two operations—which from time to time breaks out in these pages even now—had already begun.

In the July issue there is a reference to Gower's hæmoglobinometer; that a few months ago this instrument—possibly not the identical

one, but a contemporary one, we should gather from the faded condition of the standard—was supplied from a scientific institution to an officer who proposed to carry out some work on anaemia, suggests that in the intervening years little advance has been made in India at any rate in hæmatological technique. But on the other hand the instructions that to obtain the average size of the red blood corpuscles *ten* cells should be measured does make one realize that the research workers of the present day have a greater respect for mathematical principles.

We do not think that in reviewing this fifty-year old volume of the *Gazette* we can possibly be accused of jeering at our predecessors, and for the sake of any of our colleagues who may think that we are minimizing the importance of recent scientific contributions we will quote from Bernard Shaw's *Doctor's Dilemma*:

'Don't misunderstand me, my boy. I am not belittling your discovery. Most discoveries are made regularly every fifteen years; it is fully a hundred and fifty since yours was made last'.

Special Article

FRACTURE EQUIPMENT: WITH NOTES ON ITS USE

By H. R. RISHWORTH, F.R.C.S. (Eng.)

District Medical Officer, G. I. P. Railway, Byculla, and Hon'y. Visiting Surgeon, St. George's Hospital, Bombay

Part I

STANDARD EQUIPMENT

FROM an administrative point of view, standardization of fracture equipment is a useful procedure. The matter is less simple however than it appears at first sight. Surgeons differ in their beliefs and come from different schools of teaching. For the average man there always will remain a bias in favour of the methods learned at his medical school, but equally good results appear to follow different procedures with dissimilar apparatus. It should be understood, therefore, that the standard scale given below is not intended as an attempt to codify fracture procedure, nor even to dictate special lines of treatment on the subject in railway hospitals, but as a suggestion, to remedy the deficient scale of equipment now laid down as standard on many railways in India, and to make essential and less easily-improvised apparatus available in all dispensaries and district hospitals. With the exception of the selection of items in the scale, and the care given to arrive at standard dimensional requirements and specifications, no claim is made to originality.

Attempts have been made and are still being made throughout the world by committees to

arrive at standardized apparatus and standardized or approved procedures for treatment. The Fracture Committee formed of members of the staff of St. Thomas' Hospital may be cited as an example of such a committee working for an institution. In America an elaborate organization, known as the 'Committee on the Treatment of Fractures' with Charles S. Seudder of Boston as chairman, has been in existence for some years. This committee is sponsored by the American College of Surgeons. Many regional sub-committees work under, or co-operate with, the main committee. The American Medical Association has an Exhibit Sub-Committee engaged in propaganda work, and demonstrations on the treatment of fractures and the correct use of approved apparatus. The A. M. A. issued in 1930 an *Illustrated Primer on Fractures* which suggests what constitutes acceptable treatment, with illustrations of the apparatus recommended. The American Railway Association, which includes among its members 250 chief surgeons and 14,000 other surgeons in the U. S. A.—presumably railway surgeons—has Permanent Regional Fracture Committees, co-operating with the college committee to secure better treatment of fracture cases resulting from railway accidents and in railway shops. No such colossal and massed attack on the question has been attempted elsewhere.

Another attempt at standardization of fracture treatment, of a different order, is the system evolved by Professor Lorenz Bohler, head of the

Arbeiter-unfallspital of Vienna. At this institution the precise procedure and apparatus is carefully systematized for each lesion. It is a pleasure and a revelation to watch the team work organized by him in operation. The circumstances however are favourable to such an organization at Vienna, where all injured workmen are concentrated at this one accident hospital under one director. Many of the methods advocated by this teacher are original and are gaining world-wide acceptance. I am indebted to his teaching for some of the apparatus here recommended.

A valuable and earlier attempt at standardization may be found described in the *Manual of Splints and Appliances* issued by the British Red Cross Society in 1917. I strongly commend this manual to the notice of all medical officers who expect to treat fractures on modern lines with modern equipment. Details in regard to measurements and specifications of some of the splints described in this note have been obtained from this useful little book.

It will be seen that many attempts to achieve standardization are being made, but it is obvious that each organization must compile a scale to meet its peculiar needs. If this scale however is to satisfy the general worker and at the same time stand up to well-informed criticism, it must be based on broad principles of treatment which are more or less generally accepted as embodying modern views. These principles I believe to-day are

1. The use of Thomas' splint or one of its modifications, e.g., Jones', Murray's, Sinclair's, for both extremities, involving the skeleton type of splinting and the sling principle of support.

2. The use of a Balkan beam or some suitable substitute.

3. The application of direct extension to bone by calipers, ice tongs, wire, needles and stirrup, etc.

4. The increasing use of plaster of Paris as a splinting medium.

5. The abduction position for lesions of long bones situated near the shoulder or pelvic girdles.

6. Ambulatory methods where possible.

7. The passing out of general use of the flat board type of splint, e.g., Dupuytren's, Liston's, except for first aid and transport purposes.

8. The use of powerful screw traction apparatus or extension appliance in reducing or 'setting' difficult fractures, and for maintaining the limb in extension during the application of plaster or other means of fixation.

9. Greater conservatism in regard to open operation with more clearly-defined indications for its application.

10. The imperative use of radiography in diagnosis, treatment, and the assessment of results.

11. The use of local analgesia for obtaining relaxation and of course for the relief of pain.

I do not think it is possible to lay down a standard on modern lines without attention to all of these.

Turning now to the scale which is given in tabular form on page 35, it will be seen that it consists of four allotments:

- (1) Loan equipment.
- (2) Equipment for A-grade district hospitals.
- (3) Equipment for B-grade district hospitals.
- (4) Equipment for dispensaries.

The loan equipment is maintained in Bombay*. The items are available for any hospital on the line within 24 hours, on application by wire, and consist of apparatus or instruments which are not required for immediate use on the admission of a patient.

In classifying district hospitals into A and B grades the factors taken into consideration are the possession of an x-ray plant and the number of beds. In the nature of things it is unlikely that a uniform standard of surgical skill will ever be found among district medical officers. The larger districts appear to attract those with a penchant for surgical work and it appears sound policy to allot to such districts a fuller equipment than to the others. Byculla, Jhansi and Bhusaval* are for these reasons classed as A-grade hospitals. In order, however, that the limitations of a standard scale should not tend to restrict the ideas of any medical officer wherever posted, it is proposed that a standing work-order be placed with the local works at district headquarters to supply any special type of splint outside the standard scale. No modification or alteration of the actual standard items in stock should be permitted without reviewing the standard for all districts. Such modifications if permitted will inevitably result in difficulties with the ledger and possible ultimate loss or irreparable difficulty in checking equipment. It will be main up to date. The items are

with an eye to maintain all districts.

Equipment for doctor's car as recommended by the A. M. A.:

Thomas' leg splint	1
Thomas' arm splint	1
Wood splints, flat	1 set
Sheet of wadding or wool			
Tourniquet	1
Can of ether	1
Bandages and adhesive tape			

The above list takes no account of means for the transport of spinal and pelvic injuries, and I do not consider that either 'Thomas' splint or flat boards are adequate for the comfortable transport, at any rate in railway trains, of low fractures in the leg, as for instance a Pott's fracture. The point of application of traction, to secure effective extension, is too near the point of injury to permit the use of a Thomas' splint. On the other hand the medical subordinate may find it impossible to reduce the fracture well enough, without assistance, to enable flat board splints to be used effectively. For these cases I have included in dispensary equipment a specimen of the well-known Edinburgh box splint. If the limb is well packed around with wool before the sides are brought together this splint will keep a Pott's, or other low fracture in the leg, in comfort and without risk of further displacement or damage to the soft parts during a railway journey. I doubt if there is a simpler and better first-aid appliance for low fractures of the leg than this cheap and easily-made contrivance. Medical officers should however resist the temptation to use this splint for the permanent treatment of these fractures, especially where there is displacement which tends to return after reduction. Considerable deformity and shortening will result owing to the absence of arrangements for securing extension. Such cases are better dealt with on a Braun's splint with extension direct from the bone or by adhesive strapping from the skin; see figures 14 and 15. For spinal and pelvic injuries the scale includes a Bradford frame. A further note on the use of this appliance will be found below.

Fractures of the spine and pelvis have a peculiar distinction when regarded from the point of view of transport and nursing. They may bring the patient to within a narrow margin of death, and that narrow margin can be easily crossed in unskilful attempts to move him. The simplest and safest known way to move such a patient is by means of a Bradford frame. The patient should never be lifted or carried on to a cot or stretcher. A Bradford frame should be placed on him and the body secured to the frame by canvas strips. The strips are passed under the body with the least possible disturbance and securely laced to the side rods of the frame. Additional fixation of the body can be secured by sand-bags and strips passed over the pelvic and shoulder girdles. The patient can then be lifted in the frame

without undue disturbance. If the frame is arranged so as to keep the feet low, spinal extension can be secured by a chin-and-occiput bandage carried to the top cross bar. Nursing can be carried out in the same frame without any or scarcely any movement, one strip of canvas being removed at a time as occasion arises. The frame and canvas are shown in figures 6 and 6a. Six strips fill the frame and two extra ones are provided for fixation of the pelvic and shoulder girdles during transport.

No special apparatus is provided for fractures of the bones of the hand and foot. It cannot be the purpose of a standard scale to provide in detail for every contingency. The treatment of these fractures however lends itself to improvised apparatus as it requires small and easily-made appliances. The surgeon will find in the scale means to this end in the shape of plaster, tools, and Cramer's wire splinting. Some suggestions in the use of the last item will be found illustrated in figures 18 to 20.

In regard to the humerus, in addition to the straight swivel arm splint and the Jones' extension splint, abduction for high fractures has been provided for by an acroplane splint (figs. 16 and 17). This splint does less than justice to itself so far as appearances go. It is, however, light, comfortable, easy to manufacture, and can be worn continuously for long periods. Children and undersized, outsized, or deformed individuals can be fitted with improvised abduction splints made from Cramer's splinting as shown in figure 18.

A built-up fracture bed with sectional mattress and pulleys is a great convenience to the nursing staff. Except for A-grade hospitals, however, I do not think a general issue is necessary. For these three hospitals I recommend the issue of one Pearson fracture bed to each. It is superior to Souttar's beam (London Hospital), and is stronger and less complicated than Morrison's frame in use at Edinburgh.

For B-grade hospitals the ordinary bedstead (Lawson-Tait) with fracture boards and a suitable Balkan beam is satisfactory for the occasional use it will be put to. Full details for making fracture boards, standard pattern weights, bed steps and a thoroughly satisfactory type of Balkan beam will be found in figures 7, 8, 9 and 10. The beam is a take-down model for convenience of storage when not in use, adapted from the design in use at the accident hospital, Vienna.

No mention has been made of the rarer forms of fracture, which present special difficulties, such for instance as fracture of the os calcis. This scale is intended as a minimum essential to meet the requirements of the average medical officer. On the other hand I believe it may be argued that the proposed scale is actually excessive, and that some of it may probably never be used. The answer to this is simple. The probability becomes a certainty if the equipment

Figs. 11 and 11a.—For temporary treatment and transport of closed or open fractures below the middle of the leg. Not to be used for permanent treatment.

is not supplied, and this, I think, is to some extent the condition of things to-day. Fracture treatment has made great strides since the war, and unless suitable modern appliances are shown to be available, it will be difficult to meet instructed legal criticism or well-informed lay comment.

Some of the minor items of equipment such as tools, weights, sand-bags, steps for raising beds, may appear unnecessary to a certain type of mind. No need, however, is so important in fracture treatment as careful attention to detail. These minor items are really essential if annoying delays and difficulties are not to be encountered.

As far as possible each appliance recommended is described and illustrated by detailed drawings with accurate measurements. The drawings have been so contrived that the items can be easily made from them under a competent foreman*. Where it is intended, on account of the nature of the material or its construction, that an item should be purchased, the maker and the catalogue number have been given so as to ensure a good article with at the same time uniformity in design.

I have not considered it necessary to fortify this report with accurate references to literature. This is partly due to the difficulties of access to journals in a mofussil town, and partly because I believe that a scale of wide application should be based on material which has achieved sedimentation into recognized textbooks on the subject. The following publications are useful and have been referred to freely in the preparation of this note :

Injuries and Diseases of Bone. By Sir W. J. DeC. Wheeler. 1928. Baillière, Tindall and Cox, London.

Thomas' Splint. By M. Sinclair. Oxford University Press, London.

Acknowledgment

My thanks are due to Dr. S. C. Chatterjee, M.D., M.R.C.P. & D.P.H., Acting Principal Medical and Health Officer, G. I. P. Railway, for permission to publish this paper.

* It is suggested that blue prints of the diagrams be prepared and retained as standards so that the equipment can be produced at the railway works. If this is not possible for any reason, the work can be done on contract, according to the specifications given, by any one of the numerous competent surgical firms now producing quite good apparatus in India. I believe however that the former procedure, after perhaps "a little trouble," will be found an economical method, both at first issue and for subsequent replacements.

Appendices

SPECIFICATIONS AND CONSTRUCTIONAL NOTES

Thomas' leg splint.—For transport and treatment of injuries to the hip, femur, knee and leg. A padded ring attached to two rods bent in a U shape, made of $\frac{3}{8}$ inch iron. The rods are continuous at the end opposite to the ring, by a notched cross piece which keeps them $3\frac{1}{2}$ inches apart at that end. The rings uniting the upper ends of the rod are of three sizes, $11\frac{1}{2}$, $10\frac{1}{2}$, and $9\frac{1}{2}$ inches in diameter. These measurements are exclusive of the padding. The special large outside of $11\frac{1}{2}$ inches is maintained on the loan equipment. The plane of the ring is set at an angle of 55 degrees with the main direction of the outer rod. The padding should be twice as thick on the inner or short rod side than on the outer. The maximum diameter of the padding is $1\frac{1}{2}$ inches. The padding consists of soft tow covered with smooth leather. Hospital staff should see that the leather is occasionally treated with soap to keep it resilient. The inner rod is 42 inches and the outer 47 inches in length, $2\frac{1}{2}$ inches from the upper end, the outer rod is bent inwards at an angle of 145 degrees so that it may meet the ring at a right angle. The rods are therefore much wider apart at their upper ends than their lower. The rods may be bent at the knee or varied slightly in shape with the use of the bending tool (figure 21). The stitching of the leather covering for the pad should be on the under side of the ring, that is on the same side as that on which the rods are attached. The diameter of the rings should be carefully noted as the rings supplied with the breakdown equipment are too small. It is better to have large rings than rings which may prove to be too small (figure 4).

Thomas' arm splint.—A circular padded ring $7\frac{1}{2}$ inches in diameter with two rods 34 inches in length attached at right angles to the plane of the ring. The ring and rods are of $\frac{1}{2}$ inch iron. At their attachment to the ring the rods are $7\frac{1}{2}$ inches apart and at the other end they are continuous by a notched cross piece which holds them $2\frac{1}{2}$ inches apart. The padding on the ring consists of soft tow covered with soft leather, and is of a uniform diameter of $1\frac{1}{2}$ inches. The stitching of the leather should be on the same side of the ring as the rods. This splint is unsuitable for the transport of arm injuries, as the limb must be carried in the abducted position if extension, which is obtained by pressure of the ring against the thorax, is to function properly. For purposes of transport the swivel arm splint about to be described is preferable (figure 1).

Thomas-Murray swivel arm splint.—Also known as Jones' or Sinclair's modification. The ring padding and rods are similar to the last splint. The rods however at a distance of $1\frac{1}{2}$ inches from their attachment to the ring are flattened and hinged by a loose rivet. This permits the rods to be moved in a plane at right angles to the plane in which they lie. This hinged movement allows the arm to be brought to the side for purposes of transport. Extension is then obtained by counter-pressure in the axilla. For this reason this splint is unsuitable for injuries near the shoulder joint. Such injuries, for first-aid purposes, are best bandaged to the side in a sling. The swivel should on no account be made directly on to the sides of the ring. The hinge is likely to hurt the patient if this is done and the line of the rods does not lie in the axis of the limb. This mistake has been made by the firm of surgical instrument makers who have supplied swivel arm splints for the breakdown equipment (figure 2).

Jones' upper arm traction splint.—A wire ring $7\frac{1}{2}$ inches in diameter is bent across its centre. The lower half circle is padded with tow and leather the centre of the padding being thicker than the ends by a gradual transition. The maximum thickness of the padding to be $1\frac{1}{2}$ inches. The upper half of the circle is unpadded and is so bent that when the padded part is in the arm-pit or axilla the upper part arches well over the shoulder. The wire rods are attached to the

S. P. = Standard pattern.

centre of each half circle. The inner rod is 14 inches long in its first or vertical part. It passes vertically down from the centre of the padded half circle. The outer one is 18 inches long in its first part, and is so curved at its origin from the circle as to follow the profile of the shoulder and then to descend vertically parallel to but $4\frac{1}{2}$ inches from the inner rod. Both rods return to form a loop 4 inches and 3 inches wide with an indentation at their lower ends. They are then carried forward at right angles to the vertical for a distance of 12 inches being then continuous by a notched cross piece at the end. This notched cross piece keeps them $4\frac{1}{2}$ inches apart (figure 3).

Sinclair's knee flexion attachment.—This apparatus is necessary where direct extension is made from the knee with the limb in a Thomas' splint. It allows flexion at the knee without interference with the

extension (see figure 5). The rods are made of $\frac{3}{8}$ inch iron and are bent to a U shape each limb of the U being 26 inches long. They are 5 inches apart at the lower end where the rods are continuous by means of a notched cross bar, and 7 inches apart at the upper end of each rod. At each upper end of the rods a clamp is provided with a butterfly nut by means of which the appliance can be attached at any point along the side rods of a Thomas' splint. The junctions between the clamp and the rods of the flexion attachment act as hinges by means of loose rivets. The detailed construction of this clamp is to be found in the diagram referred to above.

Note.—All the splints hitherto described should if possible be finished by oxidizing the metal parts. If this is found to be too expensive they may be finished with black Japan, but the former offers a more durable

Fig. 12.

Braun's splint. (a) Side. (b) Plan. (c) Front.

Fig. 13.—Method of applying adhesive traction from thigh and leg in fractures of the femur with Braun's splint as support.

Braun's splint as used for direct traction.

Fig. 14 shows intrinsic traction from the os calcis. Pads under the knee and tendo Achilles used if necessary.

Fig. 15 shows extrinsic traction with a Balkan beam for the lower end of the femur. Counter-extension is provided by raising the bed and the splint kept from slipping down by the T-shaped adjustable device.

Fig. 16.—Acroplane or abduction splint for arm. Right and left splints different. Constructed of $\frac{1}{2}$ inch deal, and 1 inch band iron.

Fig. 17.—Band iron to be covered with leather and extended as web straps with buckles. Extension provided by means of small Salter's balance with adjusting nut on L piece.

Cramer's, Cabot's or wire ladder splinting. Suggestions for use.

Fig. 18a.—Standard piece of ladder splinting 30 inches long by $3\frac{1}{2}$ inches wide.

Fig. 18.—Abduction splint for the arm for undersized cases, children, or deformed patients.

Fig. 19.—Extension bow incorporated in plaster for injuries of bones of the hand. Pulp extension may be used with Bohler's finger splints.

Fig. 20.—Extension for thumb. Similar devices may be used for the foot. This material is also useful for cock-up splints for the wrist.

Fig. 21.—Steel bending tool for rods and bars of all splints used in this scale.

and rust-proof finish than the latter. There is of course no comparison in regard to appearance. The oxidized finish is superior.

Wire ladder-splints, also known as Cramer's wire splinting, or Cabot's wire splinting. Diagrams illustrating some of the uses to which this material may be put will be found in figures 18, 19 and 20. Other uses are:

- (1) As flat or moulded splints.
- (2) Bows for extension in hand or foot fractures.
- (3) Cock-up splints for wrist and foot drop.
- (4) Protective cages or cradles with Thomas' or Braun's splint for wounds in open fractures.
- (5) Reinforcement strips in large plasters where additional protection against cracking is required.
- (6) Abduction splints for the arm in the case of children, undersized or deformed individuals.
- (7) Double inclined planes for the lower limb for temporary splinting.

The splint is made of $\frac{1}{2}$ inch galvanized iron wire placed in parallel rows $3\frac{1}{2}$ inches apart. Cross wires of $\frac{1}{4}$ inch diameter connect these two parallel pieces in ladder form, the cross pieces being $\frac{3}{4}$ inch apart. It is not likely that our works will be able to make this splinting material. It can be had, of foreign manufacture, at no great expense. The standard size should be pieces of 30 inches by $3\frac{1}{2}$ inches. They should be ordered under the name of Cramer's wire splints from Germany. Any dealer in surgical goods will be willing to import them. They are lighter, more resilient and adjustable than wooden splints.

Balkan beam.—To be constructed of teak, deodar, good pine or other suitable light but strong wood. Measurements and the details of construction are shown in figure 7. Little further comment is needed. The wood should be varnished or polished. The angled pieces carrying the pulleys may be strengthened by means of iron cheek plates $\frac{1}{4}$ inch thick. The pulley wheels are 2 inches in diameter. They are plain iron punkah wheels. Two spare pulleys are screwed in suitable positions on the cross beam, for suspension purposes. The dimensions of the frame are designed to suit the standard pattern Lawson-Tait bedstead.

Standard pattern weights.—Uniform pattern weights, besides being convenient, add considerably to the tidiness of the ward. The discs of the design shown in figure 8 should be made of cast or turned iron and about 21 pounds in weight.

Acroplane splint.—(Figures 16 and 17.) Extension is obtained by means of a small 25-pound Salter's balance. The cost of a German article is 12 annas. The L piece with adjusting nut at the lower end of the supporting strut permits of alterations in the tension of the spring after the cord has been tied with moderate tension. The wooden parts of the splint are well padded before use. The iron bands are covered with soft leather and prolonged in the form of webbing straps with buckles. The horizontal straps are 44 inches long including the iron part, and the oblique strap which is fixed to the lower end of the vertical piece by tacks is 50 inches long. The iron bands should be well padded before applying the splint.

Bed raiser steps.—Made of deal or teak. Requires no comment (figure 9).

Bending tool of steel.—Oxidized finish. The jaws are shown in figure 21 as $\frac{3}{8}$ inch apart. They should however just take the $\frac{3}{8}$ inch rods of the Thomas' leg splint.

Braun's splint.—Made of iron strips, $\frac{1}{2}$ inch by $\frac{1}{8}$ inch. Dimensions and design given in figures 12, 13, 14 and 15.

Bradford frame.—Of 1 inch galvanized iron pipe or conduit tubing as used in the electrical department for cables (see figure 6). The canvas strips have six brass eyelets of tough quality at each end. They should be large enough to allow a $\frac{1}{2}$ inch cord to run easily through the holes. The ends and sides of the canvas should be selvaged or hemmed.

Edinburgh box splint.—This appliance should be made of $\frac{1}{2}$ to $\frac{5}{8}$ inch deal (see figures 11 and 11a for details). The sides should be held together by two straps or bandages after the limb has been securely packed into the box with wool. Care should be taken to see that the heel and malleoli are well protected and that the hollow below the calf is well supported by abundant wool padding.

Storage box for plaster bandages.—This is more than a convenience. Bandages must be at hand ready rolled and they should be stored in a reasonably damp-proof box. This should be of japanned tin with a well-fitting hinged lid. It should be 12 inches long, 8 inches wide and 8 inches high.

Sand-bags.—These should be made of stout bed ticking and of the following standard dimensions. 18 inches long by 6 inches wide. Those supplied for use on the breakdown train are too long and clumsy. Two bags of moderate length are better than one long one. The bags are issued empty and hospitals should be instructed to see that they are not filled to capacity. The bag should be stood on end when nearly full and the sand well shaken down to leave a space of 3 finger-breadths, before being closed by stitching. If this is done they will be found less liable to leak or burst and will better adapt themselves to the contour of the limb.

Flat board splinting.—These should be available in bundles of six. Each piece to be of plain deal $\frac{1}{2}$ inch thick, 24 inches long and 4 inches wide. They are essentially first-aid appliances and all dispensaries should keep a supply. A small saw is included in dispensary equipment for cutting them into suitable sizes. Small pieces are useful for stirrups in plaster extension.

Fracture boards.—Details of these boards will be found in figure 10. The figure requires no explanation. Three boards constitute a set. The dimensions will fit the standard hospital Lawson-Tait bed with a frame of 72 inches by 35 inches. Fractures which require confinement to bed cannot be treated on a spring mattress unless a rigid structure of this sort is interposed between the springs and bedding.

Adhesive plaster.—Many varieties reach us mostly of bad quality from the medical stores. The most effective brand in my experience is that manufactured by the Seamless Rubber Co., Newhaven, Conn, U. S. A., and supplied in convenient containers on reels. The standard width should be 2 inches. If wider sizes are supplied wastage occurs. The 2-inch size, if overlapped 1 inch, provides effective straps 3 inches wide for all extension purposes. The stirrups for extension should be cut from the standard pattern flat board strips. They must in all cases be sufficiently wide to leave a clearance of $\frac{1}{4}$ inch between the malleoli, or condyles and the plaster.

Pearson's fracture bed.—(It can be obtained from Messrs. Malgham Brothers, Bank Street, Fort, Bombay; the complete equipment costs Rs. 285, including mattress.)

It consists of the following:—

Bed with transverse slings; removable lifting pole at head for patient's hands; two cranked uprights at foot; Balkan bar; one short transverse bar; three Maddox blocks; six small pulley blocks with hooks; bed-pan support; and three-piece mattress.

Medical News

THE FOURTEENTH INTERNATIONAL CONGRESS OF OPHTHALMOLOGY

LIEUT.-COL. E. O'G. KIRWAN, I.M.S., Professor of Ophthalmology, Medical College, Calcutta, who was the official delegate of the Government of India at the above congress, has very kindly sent us a copy of his

report, from which we have prepared the following extract:—

This congress opened in Madrid on Sunday, 16th April, 1933, the inaugural session being held in the amphitheatre of the university under the patronage of His Excellency Senor Don Niceto Alcalá Zamora, President of the Spanish Republic, in the presence of the Ministers of Marine and Public Instruction, the Rector of the University, the Dean of the Faculty of Medicine and over 1,000 members and guests.

Professor Van der Hoeve in opening the proceedings spoke fluently in turn in English, French, German, Spanish and Italian. On behalf of the Congress he greeted the Spanish authorities and spoke with great feeling of the losses sustained by ophthalmology by the deaths of Professors Fuchs, Axenfeld, Lundsgaard, and Roselli and Mr. Treacher Collins, who had died since the last Congress at Amsterdam, four years ago. The members rose and stood in silence to their memory.

Amongst the various demonstrations on the first day was a film by Dr. Lopez Lacarrere (Madrid) showing his method of cataract extraction by coagulation with the diathermy needle, which was of outstanding merit and of special interest to the ophthalmologists working in India where cataract is so common. His method opens up a new field of operative work especially in the case of immature cataract in middle-aged persons threatened with the loss of their job from failure of vision.

Another film shown by Dr. Castroviego (New York) demonstrated experimental work with transplantation of rabbits' cornea. This was most instructive and in his technique the graft is quadrilateral, is cut with a knife, and finished with scissors. No sutures are put in the cornea, the graft being kept in position by a large conjunctival flap.

A third film shown by Dr. Lijo Pavia (Buenos Ayres) was a cinematograph picture of the pulsations of the retinal vessels seen whilst using the Baillart tonometer. Pulse records and blood pressure estimations on the same patients were also shown.

A series of colour photographs of the fundus with detachments of the retina before and after operation were shown by Sabbadini (Rome) and Lijo Pavia (Buenos Ayres).

Dr. W. Comberg's (Berlin) demonstration of the correctness of Helmholtz's theory of accommodation by means of his new slit-lamp on a subject he brought all the way from Berlin with him, and Dr. Troncoso's paper and demonstration on gonioscopy attracted much attention. Drs. Cohen, New, and Killian discussed experiments on the vitreous gel and intra-ocular tension. Dr. O. Wilkinson's paper on the surgical treatment of squint, Dr. J. Arjona's (Madrid) description of a new conservative operation for chronic dacryocystitis, and Dr. Arruga's (Barcelona) description of his procedure on the extraction of complicated cataract should be mentioned.

On the same morning the meeting of the International Association for the Prevention of Blindness took place under the presidency of Dr. Park Lewis (America).

The third day was devoted to the first main subject for discussion 'Tuberculosis of the Iris and Ciliary Body'; the discussion was opened by Dr. Brown (Chicago) who read a paper on modern methods of treatment emphasizing the fact that general constitutional treatment in healthy surroundings is of paramount importance and that ophthalmological treatment and tuberculin therapy, though necessary, are of secondary importance. Professor Igersheimer (Frankfurt) followed with an elaborate paper on the pathological anatomy of the disease, which was ably illustrated by most beautiful microscopic sections. After this Professor Lagrange (Paris) read a brilliant paper on the diagnosis and differential diagnosis of the disease, in which he stated that the histological findings are not proof positive, that the tuberculin reaction alone is hardly confirmative, and that the diagnosis is

mainly one of exclusion. Many members took part in the discussion that followed.

The fourth day (19th April) was occupied in the morning with a discussion on the report of the committee on the international standardization of the visual requirements of aviators, sailors, railway employes and transport workers.

At a meeting of the Council of the Congress under the presidency of Professor Van der Hoeve the following resolution proposed at the last International Congress at Amsterdam was passed and, on account of its importance, it should be widely circulated:—'The XIV International Congress of Ophthalmology, considering that errors of refraction are true diseases and that grave mistakes in diagnosis can result in connection with them; that the examination of the refraction of children's eyes is of extreme importance and that an inexact or incomplete correction may lead to serious consequences later on in life; that errors of refraction in the adult and still more so in the aged may indicate or be the consequence of serious local and general diseases, such as diabetes, glaucoma, cataract, etc., is of the opinion—

(a) that the examination of the refraction of the eye is essentially the work of a medical man;

(b) that this examination being the work of a competent medical man, therefore the prescription of glasses should be done exclusively by doctors;

(c) that as a consequence there are urgent reasons to call the attention of public authorities to the campaign at present being pushed in certain countries to separate the examination of refraction from ophthalmology and make it the legal prerogative of practitioners who are not medical men but style themselves optometrists or optometric opticians or refractionists'.

The fifth day was devoted to the second of the two main subjects for discussion 'Detachment of the Retina'; this discussion was received with a more lively response than the first official subject. The opening paper on the aetiology of the condition was delivered by Professor Arruga (Barcelona) who gave a comprehensive account of the experimental and clinical work done by himself and others. The discussion on the medical and surgical treatments of detachment was initiated by two opening papers by Professors Ovio and Vogt, respectively; in this many members took part. Many other original papers on detachment of the retina were also read. The result of the discussion seems to confirm Gonin's view that a detachment is caused by a hole in the retina and to him should be credited the application of methods of operative cure rather than priority in the discovery of the causation. From a number of papers, it was evident that detachments can occur without holes, and holes in the retina be found without any detachment. Spontaneous cures occasionally take place by rapid pigment proliferation in the region of the hole, or by re-absorption. Treatment of detachment by the Weve electro-coagulation procedure, or one of its modifications, seemed to be popular and to be now preferable to other methods of surgical treatment. Some new methods of therapy were put forward, such as, freezing to produce an adhesive chorioretinitis, by Giambattista, hypertonic saline injection into Tenon's capsule combined with cauterization, by Marquez, and the excision of the sclera combined with diathermy, by Hildesheimer. The workman's compensation factor in detachment of the retina was discussed in papers by Davidson, Arruga, Baudot, and Jeandelize; all agreed that the part played by trauma in its causation should be recognized.

The last day was devoted to various other papers on detachment of the retina and in addition there was a meeting of the International League for the Fight against Trachoma at which a number of interesting papers were read and discussed.

Throughout the whole week there were lavish entertainments, both official and private, to which the delegates were invited; these entertainments included

a reception at the Palacio Nacional, at which each delegate was presented to President Zamora, numerous balls, banquets, visits to places of historical and artistic interest, and a bull fight.

THE ELEVENTH ALL-INDIA RESEARCH WORKERS' CONFERENCE

The following short report of this conference is reprinted from the *Statesman* of 6th December, 1933:—

Important decisions relating to various major diseases in India were reached at the annual meeting of the All-India Research Workers' Conference, which took place in the library of the School of Tropical Medicine in Calcutta.

Major-General C. A. Sprawson, Director-General of the Indian Medical Service, presided over the Conference which was attended by delegates representing various Provinces. Major-General J. D. Graham, Public Health Commissioner with the Government of India, was Secretary.

A large number of papers relating to research work carried out during the year under the auspices of the Indian Research Fund Association were submitted, and several sub-committees were appointed to examine the work done in such important subjects as malaria, cholera, leprosy, kala-azar, rabies, plague, etc. The work on indigenous drugs and drug addiction, skin diseases, and tuberculosis was discussed at the plenary session of the Conference.

MALARIA TREATMENT

In connection with malaria, considerable discussion took place on the necessity for the provision of cheaper and more easily available treatment, to ameliorate malarious conditions in various parts of the country. A resolution was passed by the sub-committee to the effect that, apart from the heavy direct and indirect mortality caused by this disease, attacks of malaria were responsible for a large amount of labour inefficiency, and this formed an economic problem of the first importance. As in the opinion of the committee, the treatment of the sick constituted the first step in any anti-malaria campaign, irrespective of any other methods employed, it was urged that both the Central and Provincial Governments should take all possible measures, at an early date, to provide cheap and adequate means of treatment.

The malaria problem in and around Calcutta and the measures taken to control the situation were also considered. The committee expressed the opinion that the use of aeroplanes for spraying Paris green to control the breeding of mosquitoes could only be applied economically under special conditions.

CHOLERA EXPERIMENTS

The sub-committee on cholera considered experiments in connection with the use of *bacteriophage* for the prevention and treatment of cholera, and came to the conclusion that, on the evidence available, it was not possible to express any definite opinion on the subject, and recommended the appointment of an *ad hoc* committee to go into the data available. Another committee was appointed to co-ordinate the various researches in connection with cholera under the Research Fund Association.

The leprosy sub-committee considered the report of the Leprosy Commission of the League of Nations and the findings of the Leprosy Conference convened by the British Empire Leprosy Relief Association and held in Calcutta in March. It was emphasized that leprosy was one of the major diseases of India, the number of cases being 1,000,000 or more. As it was an infectious disease, the most important means of controlling the menace would be the prevention of contact between infectious cases and healthy people. The committee was of opinion that, with the small financial resources available, it was impossible, at present, to introduce compulsory isolation. The only immediate possibility

was voluntary isolation, which could be arranged for only a limited number of cases in different institutions. It was suggested that patients should be encouraged to adopt isolation in their own homes or villages.

The committee stressed the need for consolidation, co-ordination and extension of anti-leprosy work. It was urged that as leprosy was essentially a public health problem, every effort should be directed to make anti-leprosy work an integral part of the public health system. The committee recommended that a specially trained leprosy officer should be appointed in every Province where the incidence of leprosy was sufficiently large. The formation of Provincial Leprosy Boards was also suggested.

In connection with the problem of tuberculosis, substantial research grants were sanctioned, and a proposal for a tuberculosis survey of Calcutta was sanctioned.

DRUG MENACE

The report of the inquiry into the drug habits prevalent in India showed a large increase in the number of addicts to various drugs such as opium, hemp products, cocaine, chloral hydrate, morphine, etc. It was stated that the use of hemp products (*bhang*, *ganja* and *charas*) was prevalent in every part of India, and 1 to 2 per cent of the population took these drugs habitually, the addict belonging chiefly to the lower strata of society. Unlike opium and cocaine, the physical effects produced by hemp drugs were not very marked, but they led to intellectual and moral degeneration, and there was a distinct relationship between the habitual use of these drugs and insanity and crime.

It was urged that investigation into drug habits in India was very important from the point of view of public health. While considerable attention was being paid to this problem in all civilized countries where the addiction rate was less than 1 to 2 per 1,000 of the population, little had been done in India where the number of addicts was roughly 20 to 30 per 1,000.

QUARTERLY BULLETIN OF THE HEALTH ORGANIZATION

UNTIL recently the publications of the League of Nations have been irregular in appearance, and valuable reports of the Health Organization have had to find homes in various journals, where they have been difficult to trace; however, at the beginning of 1932 the League commenced to publish a quarterly bulletin. It is sincerely to be hoped that the discontinuance of this publication will be the last economy to be effected by the League, as it has already become indispensable to those interested in public health, or more especially international health, matters.

In the present number there is a very important article on housing and malaria, by Sir Rickard Christophers and Professor Missiroli. This article should be read by all malariologists, as in it is summarized all published information regarding anophelism in relation to housing in all malarious countries. The subject is comprehensively dealt with, as the article covers 128 pages. There is another article on the reform of medical education, from Vienna, and the rest of the number is devoted to the report of the Health Organization for the year ending September 1933.

An extract from the malaria paper will be found in our current topics section. The journal can be obtained from the Publication Department of the League, Geneva—price 7s. 6d. annually.

INDIAN JOURNAL OF PEDIATRICS

Few months seem to pass without our being called upon to welcome some new medical journal of British Indian origin. In many cases it is difficult to see exactly which 'long felt want' these journals supply, and even more difficult to put any conviction into our welcoming message. These remarks cannot be applied

in this case. No excuse whatsoever is needed for any step that will stimulate an interest in pediatrics in this country; this is already provided by the appalling infantile mortality rates that are the rule in every town in India. British and foreign journals on pediatrics are of very limited use in the special conditions that exist in this country and the ordinary general medical journals naturally do not fulfil the requirements of the specialist to the full extent.

The journal is to be published quarterly and the first number appeared in October. There is a foreword by Sir Nilratan Sircar in which the aims of the journal are set forth, a birthday greeting from Dr. Robert Hutchison, and an introduction by Professor Czerny of Berlin. To Dr. A. C. Ukil is allotted the honour of contributing the first scientific paper. Dr. Ukil's work on tuberculosis is well known in this country and he has given an excellent account of the subject of tuberculosis in infancy and childhood; his paper is illustrated with some useful skiagrams of children's chests. Other papers are on oedematous nephritis, normal birth-weight and birth-length of Bengali infants, physiological variations in childhood, and avitaminosis in children; there are case reports, reviews of books, and finally some very valuable extracts from current literature; these extracts mostly from pediatric journals in other countries will constitute one of the most important parts of this paper.

The editorial committee are to be congratulated on the production of a high-class specialist quarterly; the articles are well written and well edited, the printing and paper are good, and in appearance the journal will compare very favourably with similar scientific journals in Great Britain and America.

We wish it every success.

THE BERRY WHITE MEDICAL SCHOOL JOURNAL

Most of the large medical schools in India publish an indigenous journal. The practice is one to be encouraged, as it helps to form and cement a bond of fellowship amongst the teachers and students of the school. Pride in one's school must lead to a continuous endeavour to maintain, by personal achievement, the name of the school in high esteem, and this tends to raise the prestige of the medical profession in general.

A new publication of this kind is the *Berry White Medical School Journal*. The number which we have received contains some useful articles written by members of the staff of the school and some interesting essays on medical subjects by students, as well as items of news that will interest all graduates who have passed out of the school.

We wish the journal every success.

THE FACULTY OF TROPICAL MEDICINE, BENGAL

THE following students are declared to have passed the L.T.M. Examination, Session 1933:

Passed

(Arranged in alphabetical order)

1. Sharfuddin Ahmad, L.M.F. (Bihar and Orissa), 2nd medical officer, Sadar Hospital, Monghyr.
2. Harendra Kumar Baidya, L.M.F., private practitioner.
3. Susil Kumar Bhar, L.M.F., private practitioner.
4. Ram Kamal Bhattacharjee, L.M.F. (Bengal), assistant medical officer, Kaliabur Tea Estate, Assam.
5. Rajendra Nath Bose, L.M.F., mosquito sub-inspector, Calcutta Corporation.
6. Debi Pada Chakraverty, L.M.F., medical officer, Sengell Tea Estate, Kurseong.
7. Doraisami Chelliah Daniel, L.R.C.P. (Bom.), railway sub-assistant surgeon, Burma Railways.
8. Nripendra Gopal Das, L.M.F. (Bengal), private practitioner.

9. Tara Kanta Das Gupta, L.M.F. (B. & O.), private practitioner.
10. Bibhuti Blusan De, L.M.F., private practitioner.
11. Samarendra Nath De, L.M.F., private practitioner.
12. Kidar Nath Dutt, L.S.M.F. (Punjab), L.O. (Mad.), sub-assistant surgeon, in-charge, Civil Dispensary, Bahadurgarh, Rohtak, Punjab.
13. Muralidhor Kundu, L.M.F., private practitioner.
14. Mahammad Mujibur Rahman, L.M.F. (Bengal), medical officer, District Board, Mymensingh.
15. Mazhar Hussain, M.B.B.S. (Punjab), private practitioner.
16. Sheo Nath Mehrotra, L.S.M.F. (U. P.), private practitioner.
17. Prayag Naryan Misra, L.S.M.F. (U. P.), assistant house surgeon, S. S. Hospital, Benares.
18. Udayakar Misra, L.M.F. (B. & O.), medical officer, Budh Estate, Orissa.
19. Mohamud Abdur Rahim, L.M.F. (B. & O.), medical officer, Suraj Garha Dispensary, Monghyr.
20. Mohammed Sharif, L.M.F., sub-assistant surgeon (Civil), Punjab.
21. Tara Pada Ray, L.M.F. (Bengal), private practitioner.
22. Sarbans Singh, L.S.M.F. (Punjab), L.M.D. (Reserve), private practitioner.
23. Anil Kumar Sen Gupta, L.M.F., private practitioner.
24. Kamala Prasad Singha, L.M.F., medical officer, Mansur Chalk, Monghyr, Bihar and Orissa.
25. Tara Singh, L.S.M.F. (Punjab), private practitioner.
26. Sivalokanatha Iyer Venkatachalam, L.M.F., private practitioner.
27. Yuen-Yo-Ying, M.D. (Thenen-Yale College of Medicine, China), assistant professor of medicine, National Medical College of Shanghai, China, and Rockefeller scholar.

CENTRAL MALARIA LIBRARY

A MALARIA LIBRARY was founded in Rome by the Stazione Sperimentale per la Lotta Antimalarica in 1925, and an 'Index to Malaria Literature' is issued annually by the Station.

To make this as complete a central malaria library as possible we appeal to all malariologists to send us books, reports and articles on malaria.

Photostat copies of any articles in the library can be had, on request, at cost of production.

All publications and requests should be addressed to 'The Director, Stazione Sperimentale per la Lotta Antimalarica, Corso Vittorio Emanuele 168, Rome (16)'.

DRUG STANDARDS

It is notified for information of the pharmacological laboratories and drug manufacturers that small quantities of the following standard products are available for issue to those wishing to standardize their preparations according to the British and International standards:

1. British standard for digitalis folia (1928).
 2. British standard for strophanthin and ouabain (1932).
 3. Standard pituitary (posterior lobe) powder.
 4. International standard of insulin.
 5. International standard of arsphenamine (sulpharsenobenzene).
 6. International standard of neoarsphenamine.
- Applications should be made to Lieut.-Col. R. N. Chopra, I.M.S., Department of Pharmacology, School of Tropical Medicine, Calcutta.

APPOINTMENT OF DIRECTOR OF WATER EXAMINATION

THE Metropolitan Water Board invite applications from duly qualified medical men and others possessing wide experience in the chemical and bacteriological

examination of water for the position of Director of Water Examination (to succeed the late Sir Alexander Houston, K.M.E., C.V.O., M.B., D.S.C., F.R.S., LL.D.) at an inclusive salary of £2,000 per annum.

Applicants should give their age and state whether engaged in private practice; and applications should embody full particulars of the candidate's experience, qualifications and appointments held. Special attention is directed to the fact that wide experience in the

chemical and bacteriological examination of water is essential. Copies of not more than three testimonials should accompany applications; and an intimation should be given as to the earliest date on which the applicant could take up his duties, if appointed.

Applications should be addressed to the Clerk of the Board endorsed 'Application for appointment as Director of Water Examination', and must reach the offices of the Board not later than 10th February, 1934.

Current Topics

Report on Housing and Malaria

By Sir S. R. CHRISTOPHERS

and

PROFESSOR A. MISSIROLI

(Abstracted from the *Quarterly Bulletin of the Health Organization of the League of Nations*, September 1933, Vol. II, No. 3, p. 461)

A NUMBER of points have appeared in the literature regarding housing and malaria which may be said to be still open to discussion. Most of these can be now either dismissed or explained. Some of them relate to two or more separate conditions and are open to two or more explanations.

Malaria houses, if such exist quite in the form this phrase suggests, can only be regarded as houses which, for some reason, are, more than other houses, subject to one or more of the many epidemiological causes which tend to increase the prevalence of malaria in their inmates. Such houses may be specially liable to anophelism, on account of their proximity to breeding places or the extent of these. They may be specially liable to have inmates whose mode of life favours, through carelessness or otherwise, the contraction of malaria. They may have gained their malarial reputation because of their propinquity to a reservoir of virus, a common reason for the 'fever' or 'blackwater' house in the tropics. It is quite possible that some houses do have an increased amount of malaria, due to darkness and other characters favouring aggregation of anopheles, though this is not a reason probably so potent as supposed. It is perhaps even possible, in some cases in Northern Europe, that house construction or character, or the habits of their inmates, have lent themselves especially to the bringing about of an aggregation of partially hibernating female anopheles which have entered and remained, and, once having done so, must almost inevitably be a very serious cause of malaria (winter-contracted malaria). No general law probably explains such a circumstance as a house with a reputation for malaria, or even with an undisputed succession of cases, and the chief interest in our present connection lies perhaps in what degree the last explanation given—i.e., prolonged sojourn in houses, due to partial hibernation—may hold good in some countries. Otherwise, the conception that a dark, dirty, damp house suffers in proportion to its attractiveness to aggregation of anopheles is against the general trend of opinion, which is influenced by the known great mobility of anopheles under normal conditions.

Killing of adult anopheles in houses, except in the case of partially hibernating females, would not appear to be a very profitable method in ordinary circumstances. But it might be a method of great importance if partial hibernation occurred to any extent in actual houses in an area. All methods of destroying the insects would, under these conditions, have a greatly added importance.

Zoophilism is true in a very partial sense in that, in the tropics as elsewhere, cattle act as a diverting and

diluting factor in malaria transmission. The formation of zoophilic strains through selection seems no longer likely to be true, and the very marked features given to 'zoophilism' in Europe are largely due to the occurrence of a variety of *A. maculipennis* (var. *messac*) that has relatively little tendency to feed on man. Similar cases may occur in the tropics, but are more difficult to work out, owing to the large number of species usually present simultaneously in shelters. Up to the present, no such marked zoophilic form as var. *messac* appears to have been definitely recognized out of Europe.

Disappearance of malaria from some areas is probably a complex phenomenon due to various causes, but it appears to have been in some cases due to the fact that only varieties showing small association with man existed in such places and that these have been unable to maintain malaria under changed conditions, which have still further lowered their degree of contact with man. Improved housing may, however, have played its part, possibly in much the same direction. Such changes as were associated with the use of glass windows, for example, may well have played a part in lowering the degree of contact between anopheles and man.

To come to the main issue—viz, how far is house construction a means by which malaria may be controlled—it is possible to say that apparent anophelism does not always indicate the number of anopheles entering the house and leaving it and that, in proportion as the house is lighter and better ventilated, more anopheles tend to leave before morning, though under comparable conditions it is doubtful whether less enter. Any question whether a house by its open and well-ventilated condition is made less suitable to malaria becomes less important by the fact that, if malaria does exist, it is the proper procedure to screen the house and exclude the insects. If so screened, it is relatively unimportant whether such a result might have been attained in a much less degree by improving construction alone.

The results of Missiroli and others in the screening of houses as a means of protection against malaria show, not only the effectiveness of this method, but its relative ease of application. There can scarcely be any doubt, screening is the one salient feature of house character which is important and from a preventive point of view effective. Screening, however, must take note of human comfort and, in warm climates especially, construction and screening, to be effective, must go hand in hand. Next to screening in importance is the overhead fan.

Such a method of combating malaria as screening can apply under present conditions only to a fraction of the malaria problem. Yet this fraction is important. Included in it is the housing, especially of Europeans, in the tropics, which is in itself a matter of enormous importance.

Screening has a quite special application to prevention of malaria in reclaimed areas and schemes of agrarian bonifica, where the whole subject of prevention

of malaria can be taken up from the beginning and worked to. It further has a tremendous importance in regard to the malaria of pioneer settlement in tropical malarious countries, and appears to be the answer as to what is the most appropriate action to take against blackwater fever in such circumstances.

That any kind of screening is better than no screening may be true in some circumstances, but usually, in intensely malarious areas in the tropics, the truth of such a statement is doubtful. Personal protection through the mosquito net is at present the most effective form of protection open to the careful European and one the importance of which should not be subject to any doubt. To some extent, the screened house and the net are antithetic, though not so if the overhead fan be used. To know for guidance to what extent one is protected is important, and to train individuals to trust to imperfect screening is, in this, as in other ways, undesirable.

No such issue should, however, arise, for, if screening is to be carried out as a measure under responsible authorities, its effective and thorough character is of its essence, and it must be supplemented too, not only by constant inspection, but by every possible effort in propaganda and example, if it is to be a success.

Though points in regard to anophelism enter into the question of housing in relation to malaria, they have little to do with the screened house. For summary and conclusions regarding anophelism, reference should be made to the summaries given under different headings in the text of this report, in which an attempt has been made to summarize what is known on the subject. Practical effort meanwhile need not be unduly concerned with subtleties of anopheline behaviour. The issue is rather removed, for the practical sanitarian, to the sphere of human difficulties and human imperfections. It must be admitted, however, that, as yet, any relation between effective malaria prevention and improvement of housing of indigenous rural populations in many non-European countries, and, as applied to the hut in its various forms, does not seem apparent to the authors.

Current Theories of the Ætiology of Pellagra

By HARRIETTE CHICK, D.Sc. (Lond.)

(Abstracted from the *Lancet*, 1933, Vol. II, No. VII, p. 341)

I do not propose to deal with theories which have been advanced to explain the causation of pellagra other than those which are dietetic or nutritional in character. To those like myself whose knowledge is derived from a study of the literature, the case seems settled in favour of a dietetic theory. The various theories which have been put forward from time to time, involving an infective agent, have received no continued support or confirmation, and the following facts seem to admit of only one origin, a nutritional origin, for the disease:—

(1) The lack of any evidence of spread of the disease among contacts not receiving the same diet; (2) the absence of recorded instances of nurses and doctors contracting the disease from the patients attended by them; (3) the observed recovery of patients receiving an 'improved' diet in hospital, without other treatment, and the failure to do so on an 'inferior' diet.

The final proof would seem to be contained in the long series of researches carried out by Goldberger and his colleagues, showing that pellagra can be prevented or cured in populations among which the disease is endemic by adding to the diet in sufficient quantity even one only of certain simple foodstuffs, such as meat, milk, tomatoes, wheat embryo, or yeast.

In the attempts which have been made to determine the exact defect in diet by which pellagra is caused,

there are three well-established facts which have formed the basis for special study:—

(1) Pellagra is a disease of poor people in rural districts, subsisting on a limited choice of food, and is rarely, if ever, seen among the well-to-do, who enjoy a richer or more varied diet.

(2) It is almost invariably associated with the use of maize as a staple cereal in diet, and its occurrence in populations subsisting mainly on wheat or rice is something of a rarity, though well-authenticated cases have been reported. The occurrence of pellagra in recent years in the United States as the result of severe alcoholism appears, at first sight, to be another exception to the above rule; it may, however, prove to be otherwise (see below).

(3) It is a disease of warm and sunny countries, a fact which may, however, be partly connected with the fact that maize is often the cheapest cereal in such localities, as, for example, in Egypt, Italy, Rumania, and the Southern United States, where pellagra is prevalent.

The above facts must be satisfactorily accounted for in any theory which professes to explain the ætiology of pellagra, and it is especially the connection of the disease with the consumption of maize which will form the subject of this paper. For it is just in this respect that the two main theories which are current to-day break down. There are, first, the theory connecting pellagra with an amino-acid deficiency in diet; and, secondly, that associating the disease with a vitamin deficiency.

THE THEORY OF AMINO-ACID DEFICIENCY

The association of pellagra with maize consumption led naturally to the conclusion that the disease might be caused by a lack of protein of high biological value; in other words, by a deficiency in the diet of certain essential amino-acids. The proteins of maize have been shown to consist, to the extent of 58 per cent of zein, the notoriously incomplete protein lacking the important amino-acids tryptophane and lysine. The work on zein of Willcock and Hopkins, and of Osborne and Mendel, which is too well known to need description, showed conclusively that young animals fed on diets containing zein as the sole source of protein could not maintain their weight unless tryptophane was added, and were unable to grow unless lysine was given.

Zein is thus a protein of low nutritive value incapable of replacing completely the daily nitrogenous waste of the body. Maize glutenin, which forms 36 per cent of the protein in maize, is, however, more complete in the essentials in which zein is lacking, and tends to supplement the latter, when maize is consumed.

Animal proteins as a class contain a more varied assortment of amino-acids than vegetable proteins (e.g., those of cereals, vegetables, and legumes), and in this respect may be assumed to resemble more closely those contained in the tissues of the animal they are used to nourish. It is generally true that nitrogenous equilibrium can be obtained on a smaller intake of animal, than of vegetable, protein; in other words, animal proteins have a higher biological value. The observed good effect on pellagra of adding meat, milk, and eggs to the dietary can therefore readily be explained as due to the advantage of giving a richer variety of essential amino-acids.

The theory that pellagra is developed on a maize diet as the direct result of an amino-acid deficiency is therefore a reasonable and attractive hypothesis, and the last 20 years have seen many laborious investigations carried out with the object of determining the relative biological value of the proteins of the commoner foodstuffs. The experimental work has been of two types: (1) comparison of the minimal proportion of different proteins required in a dietary, as the sole source of nitrogen, in order that young animals may be reared to maturity; (2) short-term metabolic observations in which determination is made of the minimal

intake of different proteins required to maintain nitrogenous equilibrium.

WHEAT *versus* MAIZE

The sum of the work on the subject leads to the conclusion that a theory of the causation of pellagra based on a defective protein supply in diet will not explain the connection between the incidence of the disease and the consumption of diets consisting largely of maize. It is questionable, however, to what extent it is justifiable to apply the results of short term experiments on nitrogenous equilibrium, such as the above, to the case of populations subsisting largely on maize for long periods. The experience of mankind is certainly in favour of wheat rather than maize as a staple, and the latter is usually eaten from necessity rather than choice. The experimental work, in which young animals have been reared on diets containing proteins derived from one cereal only, has often given results in favour of wheat rather than maize. These experiments have, however, been criticized on technical grounds in the general review of the subject given by Mitchell, who has also pointed out that pellagra is a disease mainly affecting adults and, in this respect, differs from many other diseases of nutritional origin to which young children are especially susceptible.

THEORY OF VITAMIN DEFICIENCY

Ten years ago it would have been true to say that the current opinion, among those who had devoted most time and energy to the study of the subject, was that pellagra was the result of a defective provision of protein in the diet. Among those holding this view were Goldberger and his associates working in the laboratories of the U. S. Public Health Service at Washington. There was, however, one important observation which was not in agreement—namely, that made by Voegtlin and others in 1920, that pellagra could be cured, or influenced favourably, by addition to the diet of protein-free extracts made from the liver or the thymus gland. Other aberrant facts were those discovered by Goldberger and Tanner in 1925, who showed that the protein caseinogen, even when given in large amounts (46–90 g. daily), did not act as a satisfactory cure, often causing only temporary improvement, while excellent cures were obtained with 30–50 g. (dry weight) daily of a yeast extract which could only have contained traces of protein.

The results of experimental work with rats enabled Goldberger and his colleagues to identify the pellagra-preventive substance in yeast with a constituent of the water-soluble B-vitamin complex, and provided the proof of the fact, long suspected, that the water-soluble B-vitamin contained at least two constituents, both of which were found necessary for the continued growth and development of the rat: (1) the more heat-labile, antineuritic vitamin B₁, necessary to prevent beriberi in man and polyneuritis in birds and mammals; (2) a more heat-stable constituent, in absence of which young rats developed a pathological condition marked by a symmetrical dermatitis, which was considered to be the analogue of human pellagra. The latter dietetic factor Goldberger called the P-P, or pellagra-preventive, vitamin; it is now generally known as vitamin B₂ in Europe, or vitamin G in the United States.

A remarkable similarity is shown in the distribution of (a) vitamin B₂, as determined by experiments with rats; (b) the pellagra-preventive factor, as shown by clinical trials; and (c) the black tongue preventive factor, studied on dogs. The conclusion is irresistible that these three dietetic factors are identical.

It is, however, when the distribution of vitamin B₂ among the cereals is studied that the analogy between the experimental work and the facts of human pellagra breaks down. Aykroyd, using rats as experimental animals, made a careful study of the vitamin B₂ content of wheat, maize, rice, and millet. The cereal to be tested was incorporated as a high percentage of the basal diet, which contained all known essential elements,

including the antineuritic vitamin B₁, and the growth of young rats was observed over a period of several weeks. While these foodstuffs are low in vitamin B₂, they were found to be by no means devoid of it. Whole wheat was found to have the highest vitamin B₂ content, then whole maize, and lastly unmilled rice and millet; animals receiving 30–50 per cent of rice in the diet grew very little more (4 g. average weekly increase) than those on the basal diet without cereal supplement (3 g.). The endosperms of wheat (white flour), of maize (maize grits, maize flour, hominy), and of rice (polished rice) were found to be of an equal, but low, value. The very definite superiority in vitamin B₂ content of whole maize over unmilled rice and millet, and the lack of evidence of any inferiority of maize endosperm as compared with that of wheat or rice, are facts which fail to explain the connection of pellagra with the consumption of maize, whether in the unmilled or milled form. If pellagra were indeed caused by a simple deficiency of vitamin B₂ it should occur chiefly where populations subsist on poor diets containing rice, rather than maize, as a staple, and it should be no more frequent among those nourished chiefly on maize products than among the poorer classes in countries where wheat is the cereal used. This, however, is not the case. Among rice-eating people, beriberi and not pellagra, is the menace to those whose diet is lacking in supplementary foods, and this is also true where the food consists too exclusively of white wheaten bread and flour, as, for example, was found by Aykroyd in Labrador and Newfoundland.

THEORY OF A MAIZE TOXIN

While both the theory of amino-acid deficiency and that of vitamin deficiency give a satisfactory explanation of many of the facts connected with the etiology of pellagra and with its prevention and cure, both fail to account for one very characteristic feature—the usual association of the disease with the consumption of maize. There remains, however, a hypothesis which has received many adherents in the past—*viz.*, that maize contains a definite poisonous substance and that pellagra is caused by its toxic action. The literature on pellagra published in the second half of the nineteenth century is almost entirely concerned with this theory and the evidence, clinical and experimental, in its favour. Most of this emanated from Italy, where pellagra at that time was recognized as a serious menace, and was the subject of intensive study.

The occurrence of the skin lesions on exposed parts of the body in pellagra led to the idea that maize might contain a photo-sensitizing substance analogous to that contained in buckwheat, and this suggestion received experimental support in the oft-quoted experiments of Horbacewski.

The toxic substance separated from maize and other cereals by Stockman and Johnston caused paralysis in monkeys and other animals, but no mention is made of dermatitis and other skin lesions.

In more recent years Jobling and Arnold have produced experimental evidence that toxic substances are produced in the intestine as a result of a maize diet. Fungi (supposed by these authors to be derived from the maize ingested), producing fluorescent substances in culture, were isolated from the faeces of 5 out of 9 acute, and of 2 out of 23 chronic, cases of pellagra, and in no instance from the faeces of 50 non-pellagrous persons examined. Extracts of the fluorescent material when injected into mice were found to render these animals sensitive to light; they developed swelling and oedema of the eyelids, reddening of the ears, and death occurred in some cases. This very suggestive work has received no published confirmation in the intervening years; the authors state that the disappearance of the disease in their locality prevented continuance and completion of the work.

A recent series of observations by Sabry on treatment of pellagra in Egypt by injections of sodium thiosulphate are interpreted by the author as showing a specific

action of this drug in neutralizing a toxin derived from maize circulating in the blood. This toxin is identified with dioxyphenylalanine (dopa) a substance nearly allied to tyrosin, and is held to be responsible for the characteristic skin erythema and the hyper-pigmentation on the exposed parts.

In view of these suggestive, if contradictory, results, it seems likely that the search for a toxic substance in maize and maize products is deserving of more attention in the future. There has been, and still is, a persistent conviction in many quarters among those in direct contact with the disease that deteriorated maize is particularly liable to cause pellagra, an idea reminiscent of the analogous theory, often advanced, that beriberi is frequently connected with the consumption of damaged rice. Experiments at the Lister Institute have given indications that maize diets which have been kept rather too long before feeding may be unwholesome, in comparison with similar diets containing wheat products. The results are not, however, consistent, and further experimental work on this point is needed and might yield valuable results.

A THEORY COVERING THE KNOWN FACTS

An attractive hypothesis that seems worth exploring would be that pellagra is caused by some toxic substance derived from maize which is rendered innocuous by the action of the P-P (pellagra-preventive) vitamin or vitamin B₃, if present in sufficient quantity in the diet. Such a theory would explain the observed curative and preventive action of the food—yeast, liver, milk, and meat—all of which are rich in this vitamin. The fact that maize is no poorer in vitamin B₃ than other cereals would then be no stumbling-block, since pellagra would naturally tend to develop on one-sided diets consisting largely of maize. For such diets would require an extra provision of vitamin B₃ to counteract their toxic properties and to ensure correct nutrition, and if the foods required to supply the necessary amount of vitamin B₃ were not forthcoming in the other constituents of the diet, the occurrence of pellagra would be expected.

The conception of a dietetic disease being due to a positive toxic agent combined with a vitamin deficiency is not a new one. There are many analogies: indeed, one of these dates from the discovery of the first vitamin.

A following theory of the cause of pellagra is suggested: *Pellagra is caused by a toxic substance derived from the maize diet, which can be corrected by sufficient 'good' protein, or perhaps by sufficient vitamin B₃ (which is found to accompany the 'good' proteins).*

The symptoms of vitamin-B₃ deficiency as studied in the rat—the irregularity of the occurrence of the dermatitis and the frequent absence of severe intestinal symptoms—throw some doubt on any supposition of identity between this condition and human pellagra. It is possible that the effective antidote to the maize toxin is neither the 'good' protein, nor the vitamin B₃, but in reality some unknown water-soluble substance which is found with these in nature or derived from them in the animal's economy.

The occurrence of pellagra in the United States among severe alcoholic addicts, which is reported to be increasingly prevalent and to have been relatively infrequent before the period of prohibition, is possibly connected with the fact that the illicit liquor may largely consist of 'corn whisky' distilled from maize products. The habit of the alcoholic addict to take little other food during periods of excessive indulgence would explain the failure to neutralize poisons derived from the maize liquor. Alcoholic pellagra has rarely been reported in those parts of Europe, where whisky is distilled from barley, and where none of the usual strong liquors are derived from maize. In Rumania, however, where pellagra is a prevalent disease at the present time, maize frequently the staple cereal and 'whisky' often distilled from maize, the idea of an

association between pellagra and the excessive consumption of alcohol is widespread among both the medical profession and the laity.

The suggestion put forward above that pellagra may be caused by a toxin derived from the diet, which can be corrected in the presence of certain foodstuffs (such as meat, milk, eggs, green vegetables) if given in sufficient quantity, is, at present, a speculation. It might, nevertheless, serve as a useful working hypothesis to those studying the aetiology of pellagra whether by the experimental or clinical method. It is put forward in the hope that by its use research may be stimulated in certain directions, which may result in further progress toward the solution of the mystery which at present shrouds the cause of the disease.

(Note: A similar theory was put forward some years ago by Aeton and other workers at the Calcutta School of Tropical Medicine regarding the aetiology of epidemic dropsy; however, experimental proof of the neutralizing power of the vitamin concerned was not forthcoming. Editor, *J. M. G.*)

Amoebic Liver Affections: Symptoms and Treatment, with a Review of 25 Cases

By PROF. A. G. BIGGAM, O.B.E., M.D., F.A.C.P.
MAJOR, R.A.M.C. (SECD. F.O.)

and

Dr. PAUL GHALIOUNGUI, M.D., CH.B.

(Abstracted from the *Journal of Tropical Medicine and Hygiene*, 15th Sept., 1933, Vol. XXXVI, p. 270)

SINCE the introduction of emetine and other more recent drugs in the treatment of amoebic dysentery, amoebic liver abscesses have become relatively uncommon in Egypt, but cases still occur from time to time.

The following observations are based on 25 cases of amoebic liver involvement admitted during the last eighteen months in which definite abscess formation was present, or where such a marked liver enlargement was found that the presence of an abscess was considered extremely likely.

Amongst these 25 cases only one was a female, and she suffered from amoebic hepatitis which did not progress to abscess formation. The relative immunity of the female sex in this series coincides with other observers' experience.

This greater frequency in males is probably due to the much higher incidence of dysentery in male patients, a well-known fact in admissions to Kasr-el-Aini Hospital. This may be due to the lesser risk of infection of females who, living mostly indoors, are less exposed to the risk of eating and drinking contaminated food and water.

Are we justified in concluding from this difference between the relative incidence of amoebic enteritis and that of amoebic hepatitis in the male and female sexes that males, if affected with dysentery, are about one and a half times (11 to 6.55) more liable to hepatic complications?

Alcohol, as suggested by some authorities, does not seem to be an important aetiological factor in Egypt, being forbidden by the Mohammedan creed; besides, in the majority of our cases there was no suggestion of indulgence in alcohol. Spices are equally partaken of by both sexes.

HISTORY OF DYSENTERY

This could be obtained in 13 out of the 25 cases, that is, in about 52 per cent. Vegetative forms of amoebae were found roughly in a quarter of the cases, while sigmoidoscopic evidence was positive in 6 out of 10 cases investigated by this method, the remainder of the cases not being examined as their general condition on admission contra-indicated the fatigue of proper preparation and examination. The interval between the first history of dysenteric symptoms obtainable from the patient and the onset of the hepatitis varied from one case with the onset of hepatic and intestinal

symptoms appearing together to one case where an interval of twelve years elapsed before hepatic symptoms were complained of, eight cases out of 13 occurring within six months.

Eight cases still had intestinal dysenteric symptoms on admission, while two developed hepatitis while under treatment for their dysentery.

ONSET

The first symptom was pain in 23 cases out of 25. Fever and rigors accompanied the pain in seven; of the two cases who had had no local pain, symptoms began in one as a perforated amœbic ulcer of the large intestine with generalized peritonitis. Before death dullness of the right base was detected and 200 cubic centimetres of brownish offensive pus were evacuated. In the second case the patient complained only of an epigastric tumour which proved to be a liver abscess.

The onset of hepatic symptoms was usually gradual, being sudden in only three cases.

The pain was most marked: over the subcostal region at the costal margin in six cases; in the thoracic wall above the subcostal margin in five cases; over the abdominal wall in nine cases; both above and below the costal margin in three cases.

It usually consisted of a dull heavy pain, but later a stabbing, lancinating element was frequently added to it, localized over the area of previous maximum tenderness, and aspiration over this point showed the abscess to be situated just underneath.

Shoulder pain of a dull rheumatic character was marked in seven cases, five over the right, two over the left shoulder occurring respectively in cases of right and left lobe abscesses. In one case the pain was localized deep in the armpit, but in all the others its site was over the acromion.

In five of these cases the abscess was situated in the upper part of the liver, while in the other two only a hepatitis was present. Not frequently the patient gave a previous history of recurring attacks of pain in the liver region of a similar nature to that found on admission.

CACHEXIA

The larger collections were associated with the most marked cachexia.

In the four cases that were cured by emetine alone without aspiration, wasting was not a prominent feature.

Slight jaundice accompanied the cachexia in five cases, consisting only of a subicteric tinge of the conjunctivæ and some earthy discoloration of the skin. In one of these cases no jaundice was present on admission, but the patient gave a history of slight jaundice one month prior to coming to hospital.

FEVER

Fever was absent throughout the illness in seven cases; it reached 100.4°F. in 13 cases; from 100.4°F. to 104°F. in five cases.

Patients with large collections of amœbic material showed only a moderate degree of pyrexia, while of the four cases showing high temperature two had a simple hepatitis and one was secondarily infected. This indicates how variable the temperature may be, and that a hepatitis may be either afebrile or cause a high swinging temperature, while very large abscesses are usually accompanied by moderate pyrexia only.

LEUCOCYTOSIS

The average count was 17,220, polymorphonuclears 70 per cent, lymphocytes 22 per cent, hyalines 5 per cent, eosinophils 1 per cent, the maximum being 37,400, the minimum 10,000.

The maximum hyaline count was 16 per cent in two cases, while the average was 5 per cent.

SITUATION OF THE ABSCESS

The enlargement of the liver was chiefly upwards in six cases, downwards in ten cases, both upwards and downwards in nine cases. In 13 cases the liver extended more than three fingers below the costal margin.

The situation was usually anterior; in only three cases was it posterior, and aspiration carried out from behind.

The left lobe was affected alone in three cases, and in another two cases both lobes appeared to be affected. In one of these pain was localized in the left side.

In another case the enlargement was in the middle line with left shoulder pain. The swelling was wholly abdominal and subsided under emetine treatment without aspiration.

The lungs frequently showed some signs of congestion, bronchitis or crepitations; in one case there was acute pleurisy and in another a lung abscess secondary to the liver abscess was discovered. In a third case the patient complained of a bitter taste of the sputum which had a rather yellowish tinge. Here the discoloration disappeared from the sputum after aspiration of the liver collection had been performed; had aspiration not been done, rupture into the lung would almost certainly have occurred.

After the lung complications, we found spread of the liver condition to the parietes to be the next most frequent occurrence. One case was admitted with a fluctuating swelling in the abdominal wall, and it was difficult to determine from ordinary clinical examination whether the abscess was a primary staphylococcal collection in the abdominal wall—a not infrequent occurrence in Egypt—or an hour-glass abscess extending from an amœbic liver condition. Exploration with a needle and syringe showed the fluid to be chocolate-coloured amœbic material and aspiration of the underlying liver collection was then successfully done.

A second case showed a small fluctuating swelling in the eighth intercostal space below the angle of the scapula with an impulse on coughing. There was also a second elongated swelling extending up the back superficial to the erector spinæ muscle as high as the first dorsal vertebra and as low down as the sacrum. The diagnosis of cold abscess or of a localized pointing empyema was considered, but exploration revealed thick liver-coloured material and aspiration of the liver in this situation removed 250 c.c.; attempts to aspirate the swelling along the lateral margin of the spine failed to withdraw anything, but on removing the needle and applying pressure on the swelling directed towards the site of the puncture watery brownish-coloured fluid was expressed and the swelling subsided. The case recovered rapidly without further aspiration.

These two cases show of what assistance exploration may be in the diagnosis of doubtful fluctuating swellings.

In the third case after aspiration the pus re-accumulated, the abscess pointing through the abdominal wall.

Another patient had on admission an abscess forming a localized epigastric tumour. Before he could be aspirated this abscess ruptured into the peritoneal cavity, the epigastric tumour disappearing. The patient was found in a state of profound collapse with shifting dullness in his abdomen. The peritoneal fluid was tapped and he made an uneventful recovery.

In all, seven cases showed involvement of surrounding organs or tissues. It may be mentioned here that in practically all cases operated upon previous to the series here reported, the liver was found adherent to the parietal peritoneum, this preventing leakage of any abscess material into the general peritoneal cavity during aspiration, while in no case aspirated either through the abdominal wall or through the chest did any mishap occur, the cases all recovering completely.

Displacement of the mediastinum and heart does not take place to such a marked degree as occurs with collection of fluid in the pleural cavity, and this may occasionally be of some assistance in differentiating a collection below the diaphragm from one in the pleural cavity. In the 25 cases here described five showed displacement of the heart to the left in large right-sided liver abscess, and one to the right in a left-lobed abscess. X-ray examination was found of considerable

help in the diagnosis of amœbic involvement, usually showing elevation or fixation, or both, of the dome of the diaphragm corresponding to the site of the abscess.

In cases, however, where secondary lung involvement was present, x-rays not infrequently failed to demonstrate the position of the diaphragm owing to the increased density of the diseased lung above or the presence of fluid in the pleural cavity.

In cases where the lower part of the liver was principally involved, little or no elevation of the diaphragm was present, but the movements were limited, and even this limitation of movement was sometimes absent.

TREATMENT

The routine treatment adopted in these cases was to commence with emetine gr. 1 or 2, depending on the general state of the patient; this was continued for five to seven days before aspiration was attempted, provided the patient's condition justified delay in evacuating the collection. The treatment with emetine was given in order to liquefy the abscess material and make it more easily aspirated, as previously we had frequently experienced considerable difficulty in aspiration owing to the thick nature of the material. Another advantage in the preliminary emetine treatment is that in cases where doubt exists as to whether an abscess is actually present or only hepatitis, and this is not infrequent, the treatment assists in determining whether aspiration is necessary or not. Two cases on clinical examination suggested a definite collection of pus; in one of these the liver reached the level of the iliac crest and formed a rounded, nearly hemispherical swelling. The leucocytic count was 18,000 with 80 per cent polymorphs, while the patient suffered from rigors and intermittent fever. Puncture was postponed for a few days and under emetine everything quickly subsided.

In another case the liver extended from the fourth space above to the umbilicus below. X-rays showed the right diaphragmatic dome to be fixed and raised while there was considerable abdominal rigidity and tenderness. The leucocytic count was 37,400 with 79 per cent polymorphonuclears. After the third emetine injection the liver had so definitely receded and the symptoms so markedly subsided that puncture was postponed, and later was not found necessary.

It is important to remember that some cases of amœbic hepatitis may show considerable delay before responding to emetine treatment. One case began to show improvement only after the eighth grain had been given, the liver subsequently subsiding without any operative interference. In this patient, owing to delay in diminution of the liver swelling, it was considered that an abscess was most likely present but aspiration entirely failed to reveal any pus.

As regards the toxic effects of emetine we consider that in addition to observations on the heart sounds and on the area of cardiac dullness it is important to keep a daily record of the blood-pressure as an indication of the action of the emetine on the cardiac muscle, a falling blood-pressure usually demanding care in the further administration of emetine. These blood-pressure records were frequently found of value.

The blood-pressure was frequently low before commencing treatment, and in these cases $\frac{1}{2}$ gr. doses were given. If during the course of treatment the blood-pressure fell considerably, one or two days' rest was given.

We have found that the blood-pressure not infrequently shows a rise after aspiration of the abscess despite the administration of emetine, this being apparently due to the removal of toxic material.

The only other complication of emetine we observed was in one case a generalized desquamation of the skin which subsided after stopping the drug. The subcutaneous method of administration was found less painful than the intramuscular.

We wish to emphasize the absolute inefficiency of any other amœbicidal drug to influence the hepatic process.

In one case under stovarsol per os and yatren 2½ per cent per rectum, an abscess actually developed while under treatment with these drugs, and in another under emetine bismuth iodide 3 gr. daily and yatren per rectum a liver abscess formed and spread through the diaphragm, causing an abscess of the lung. Emetine by injection is apparently the only drug that can affect the *Entamoeba histolytica* in the liver. As its effect on the gut is much less certain and lasting we consider it advisable to associate it with treatment by yatren per rectum. This plan we have recently followed in our cases with very excellent results.

SITE OF PUNCTURE

The site chosen was the most tender point, whatever its situation. This, besides showing the probable point where the abscess is nearest to the surface, frequently overlies a patch of previous pleurisy or peritonitis where adhesions have formed.

In eight cases the site chosen was above the costal margin, two being done in the posterior scapular line, two in the mid-axillary line, three in the anterior axillary line, and one in the left chest anteriorly. In four cases puncture was made in the abdominal wall. In one case we aspirated a lung abscess through the right axilla with complete success.

When carrying out aspiration of these liver abscesses careful local anaesthesia with novocain through a long fine needle was first performed. We sometimes found, after inserting this needle for anaesthetizing the site of puncture, that amœbic pus could be withdrawn through it into the anaesthetizing syringe even though the needle was a fine-bored one.

After anaesthesia aspiration was performed with Potain's apparatus, using the thickest bore needle and while this was being carried out a drop of pus was examined, both fresh and stained, under the microscope and subsequently a specimen was sent to the laboratory for culture.

During aspiration the position of the point of the needle was directed to different situations in the abscess until all the pus had been aspirated. Usually the wall of the cavity could be felt to contract down on the needle and soon, instead of feeling it absolutely free, it was found to be surrounded by solid tissue. Sometimes this contraction of the walls of the abscess would block the free end of the needle, which would have to be withdrawn a little before more pus could be obtained. During the withdrawal of the fluid the liver, by palpation and percussion, could be shown to contract down often to a remarkable degree.

In one case where the liver extended across the abdomen at the level of the umbilicus, before aspiration we had considered the possibility of two abscesses, one in the left lobe and a second in the right lobe, but on aspirating 3,650 c.c. from the right side complete subsidence of the swelling took place, showing that it must have been a solitary collection displacing the left lobe. There was only one case in which we definitely diagnosed two separate abscesses. Aspiration was undertaken first in the left seventh space and as some swelling still persisted after withdrawal of all the fluid a second aspiration through the abdominal wall midway between the umbilicus and the xiphisternum was carried out and the second collection emptied.

The shape and extent of the abscess cavity could usually be accurately estimated by careful manipulation after insertion of the needle.

One or two aspirations were usually sufficient, but in one case it had to be repeated three times and in another four times.

Where the pus withdrawn was obviously septic, as shown by the presence of numerous pus cells and organisms under the microscope, the case was referred to the surgeon.

In one case where the material was found to be septic in nature, operation revealed multiple streptococcal abscesses, and in another, a patient coming from Palestine, a suppurating hydatid cyst was found at operation, a condition of extreme rarity in Egypt. This was opened, evacuated, filled with iodoform glycerine paste and drained. The patient recovered completely.

The colour of the pus was of the typical chocolate or anchovy sauce appearance. Occasionally, on commencing the aspiration, a yellowish-coloured fluid was obtained, but as aspiration proceeded the typical anchovy appearance was seen. In one case an abscess of the lung was shown to have occurred secondary to a liver abscess by this characteristic colour. Where many aspirations were done the pus was usually thinner and darker in the later ones.

The consistency of the abscess material was usually fairly thick especially towards the end of an aspiration, and considerable patience was required as the needle tended to get blocked during the process.

No amœbæ were found on microscopical examination of the withdrawn material, only debris was seen with very rarely a few pus cells. In a number of cases, however, mild infection with staphylococci or Gram-negative bacilli was present, but this did not necessitate anything more than aspiration, the condition subsiding despite the signs of slight infection.

SUMMARY

(1) Twenty-five cases of amœbic involvement of the liver were reviewed.

(2) The rarity of its occurrence in females is stressed, this in our opinion not being influenced by alcohol or nature of food, but more by exposure to and occurrence of amœbic intestinal infection.

(3) The average age was 35, but one case is described where an amœbic abscess occurred at the early age of 3 months.

(4) In only 52 per cent of cases was a history of dysenteric bowel involvement obtained.

(5) Fever was often absent.

(6) The average leucocytic count was 17,000. polymorphonuclears 70 per cent, lymphocytes 22 per cent, hyalines 5 per cent, eosinophils 1 per cent.

(7) The situation of these abscesses is discussed.

(8) Seven cases with involvement of surrounding structures occurred: three in the lung, three in the parietes, and one ruptured in the peritoneal cavity.

(9) The importance of treatment with emetine by the subcutaneous route is emphasized, two cases being described where amœbic abscess formation apparently occurred during other recognized methods of treatment for intestinal amœbiasis. Where the condition of the patient allows of delay, emetine treatment prior to aspiration is considered advisable, this leading to cure in certain cases where abscess formation was suspected, and assisting liquefaction of the contents and diminution in the congestion of the surrounding liver where abscess formation had already occurred, thus making the aspiration a safer and easier procedure.

(10) The importance of recording daily the blood-pressure in addition to other methods of determining the effect on the heart is emphasized as an indication to the effect of the emetine on the myocardium.

(11) The best indication as to the point to select for aspiration where there is no other definite localizing indication is the site of maximum tenderness whatever its situation. A wide-bored needle is essential.

(12) Examination of the pus at the time of aspiration, naked-eye and microscopical, was found to be of considerable assistance in determining the line of treatment to be followed, the presence of numerous pus cells and organisms suggesting the advisability of an open operation.

(13) In certain cases, despite the presence of a few pus cells and organisms, aspiration with emetine was found to bring about a cure.

(14) Aspiration is considered to be the most satisfactory line of treatment in amœbic liver abscess where no contra-indication to this line of treatment exists.

The Modern Treatment of Venereal Diseases

By L. W. HARRISON, D.S.O., M.B., Ch.B., F.R.C.P.E.

(Abstracted from the *Practitioner*, October 1933, Vol. CXXXI, p. 443)

GNORRHOEA

It is often said that the modern treatment of gonorrhœa affords no better results than did that of twenty or thirty years ago; such a view is unwarranted. Certainly to the casual observer the average attack of gonorrhœa seems to last as long to-day as it did in earlier times, but, if end-results are compared, the superiority of modern methods is obvious to anyone who has practised in this branch for more than twenty years. Formerly the determination of cure was very uncertain, depending mainly on the absence for a few days of visible discharge; now in good hands the patient is not dismissed as cured until prolonged observation with many bacteriological tests have failed to disclose gonococci. The treatment of chronic gonorrhœa was haphazard, and its cure was more a matter of good luck than good management; now the up-to-date worker proceeds on systematic lines to discover the cause of the chronicity and concentrates on that, with consequent shortening of the attack. Treatment methods were more violent, and the mucous membrane of the urogenital canal was often left in a permanently unhealthy condition; to-day the infrequency of urethral stricture as compared with earlier times testifies to the superiority of the milder, more rational, more precise and thorough treatment now practised by good workers.

Probably most of these would agree that the longer they have worked at the problem of evolving a sound treatment of gonorrhœa the more they have become convinced of the paramount importance of two principles to be observed, namely the maintenance of efficient drainage and the stimulation of an adequate resistance to the gonococcus. There is nothing new in the principle that efficient drainage is essential to the cure of a microbial infection, and its importance in gonorrhœa has been recognized for a number of years, though it still seems often to be overlooked by some who attempt to stem the flow of purulent discharge in the acute stages by applying strong astringents, and in the later stages, instead of searching for and concentrating their treatment on those parts of the urogenital tract where colonies of gonococci are more or less locked up below the surface, try blindly the passage of sounds, massage of the prostate, courses of vaccines and other methods they have read of as being good for chronic gonorrhœa, without any definite idea of what any of these things is doing for the particular patient. The importance of resistance has been recognized in a general way, but the difficulty has been to gauge it. For example, those who treat gonorrhœa rationally know that it does not pay to bludgeon the tissues with strong chemicals and that the patient must not do things which tend to lower his general fitness. It has often been noted, also, that such a complication as epididymitis or a peri-urethral abscess has brought an attack of gonorrhœa abruptly to an end, and it has been supposed that the complication must have generated such a large production of antibody as to annihilate the micro-organisms. But, except for the observation that the strength of the complement fixation reaction with a gonococcal antigen is commonly raised by a complication of gonorrhœa, it has not been generally recognized that this test is a practical gauge of the patient's resistance. D. Thomson, when working at the Military Hospital, Rochester Row, during the war, found that, coincidentally with the clinical improvement of a refractory case under well-regulated vaccine

treatment, the titre of the complement fixation rose. More recently P. A. Clements, investigating at the Venereal Diseases Department, St. Thomas's Hospital, the effects of a special vaccine prepared by J. Oliver on the principles elaborated some years ago by Dimond, has confirmed this observation. He has found that in many intractable cases of gonorrhoea, cases mostly with a very slight discharge containing gonococci in which the disease has persisted for months in spite of careful treatment, the complement fixation reaction has been negative or only doubtful, and that when the administration of the special vaccine has been followed by a marked increase in the strength of the reaction to strongly positive, all symptoms and gonococci have disappeared; conversely, when the reaction has not increased in strength the disease has remained. Here it may be mentioned that I have often seen cases of chronic gonorrhoea with negative complement fixation reactions after courses of ordinary gonococcal vaccine, and see in this an explanation of the difference of opinion on the value of the vaccine treatment of gonorrhoea. The gonococcal complement fixation test shows that gonococcal vaccines differ considerably in antigenic power and also that patients differ in their response; a given vaccine may fail to raise the titre of the reaction in any case while another may fail in some but succeed in others. The value of the complement fixation test lies in the fact that, by it, one can judge much more quickly than by observation of clinical effects whether or not a vaccine is effecting its purpose. Again, in a number of cases studied in the investigation just mentioned it has been found that, when the complement fixation reaction was strong but the disease persisted, one could be practically certain that the sole requirement for cure was the discovery and treatment of badly draining foci.

The above general remarks may explain the following sketch of what I believe to be sound treatment of average cases of gonorrhoea. In acute gonorrhoea of males it is generally agreed in this country that there is little to be done at first besides washing the urethra twice daily with a mild lotion and that this is better done with an irrigator than with a syringe, provided that the irrigator is placed no higher than 3 to 3½ feet above the urethra. Personally I believe in allowing the lotion to flow into the bladder as soon as the patient has acquired the knack of relaxing the compressor urethra, but not in forcing the sphincter by using strong hydrostatic pressure; another condition is that only mild, comparatively non-irritating lotion is used. As to the nature of the lotion, potassium permanganate, 1 in 12,000 to 1 in 8,000, seems to be as useful as any and better than most for average cases, but, as changes, acriflavine (1 in 5,000), mercurochrome (1 in 2,000 to 1 in 1,000), mercury oxycyanide (1 in 8,000 to 1 in 4,000), protargol (1 in 1,000) and silver nitrate (1 in 20,000 to 1 in 10,000) may be found useful. With regard to general treatment, regular hours, mild, unspiced food, and abstinence from alcohol and spiced drinks are essential. Medicines are not really necessary in the majority of cases, but a sedative diuretic with belladonna in it seems to be useful in allaying spasm. With regard to vaccine treatment, I prefer now to wait until the symptoms have abated, regarding the vaccine as a mild spur to be used when the tissues appear to be flagging in their efforts to throw out the gonococcus. If and when the symptoms have settled down to a morning gleet with clear urine containing heavy threads and the patient seems to be making no further progress towards recovery, it is essential to make a thorough and detailed examination to discover the cause. It lies in defective resistance or/and in one or more badly draining foci. The blood is tested for the complement fixation reaction, and if this is not found to be strongly positive, vaccine treatment is instituted. It is impossible to give precise directions for the administration of vaccines because so much depends on the make of vaccine employed, and moreover patients vary greatly in their response. Generally, however, I believe that

the intracutaneous route is better than the subcutaneous, and I would start with a very small dose, say, 10 millions, which is increased by about 50 per cent at intervals of 3 to 4 days until a definite reaction occurs in the form of a well-marked area of irritation round the site of the injection, a rise of temperature to 99°F. or perhaps 100°F. and a slight increase in urethral discharge. Thereafter I would give the vaccine once a week, increasing the dose in a way which I calculate is likely to provoke such reactions as the above. The blood is tested after two or three weeks, and if the complement fixation test has not increased in strength I consider it as an indication for changing the vaccine or its method of administration. The search for the badly draining focus can be very tedious, and I doubt if many general practitioners would find it worth while to spend the time which a thorough examination of this kind entails. The first essential is to discover if the trouble is confined to the anterior urethra, and, to determine this, the anterior urethra should be washed out thoroughly before the specimen of urine is taken. If this specimen is perfectly clear and threadless, and the prostatic and vesicular fluids are found to be free from pathological elements, one can concentrate on the anterior urethra with reasonable certainty of discovering the defect. Shrewd palpation of the urethra is valuable as it may disclose abnormal thickenings which can be investigated more thoroughly later with the urethroscope. Naturally a careful search for para-urethral canals is necessary, and the urethroscopic examination must be very searching as some foci can be very small and innocent-looking. When any focus is found I open it with the electric cautery, being afraid of using a knife in auro-urethroscopy because of the risk of air embolus. The opening is followed by systematic dilatation, at intervals of 5 to 7 days, with a Kollmann dilator. If the prostate and/or vesicles are at fault, periodical massage is best supplemented by diathermy applied to this part through the rectum with a suitable electrode, the neutral pad being on the abdominal wall.

In the treatment of gonorrhoea in females similar principles are observed. Drainage is helped by douching the urethra and vagina daily and by insertion into the vagina of a dressing of gauze soaked in glycerine medicated with some mild antiseptic; a yard of gauze folded lengthwise in four is a suitable size for the dressing, and it is paid off into the upper part of the vagina leaving a tag outside for ease of removal next morning. In cases where the patient finds it impossible to attend frequently for treatment on these lines I have found that the application of 10 per cent freshly prepared mercurochrome-220 every 5 to 7 days is very useful. The vagina and cervical canal are first thoroughly cleansed by swabbing and then an urethroscopic swab soaked in the mercurochrome is inserted into the cervix. It is left there whilst the vagina is painted down with mercurochrome and then a fresh swab is inserted into the cervical canal and left there for a few minutes. The patient is instructed to douche daily with a mild antiseptic. The vaccine therapy is on the same principles as in the case of males.

It is impossible in the available space to describe at all adequately the treatment of complications, and I can say only that for abscesses such as peri-urethral or Bartholinian I prefer aspiration followed by injection of electrargol or of 1 per cent mercurochrome to incision. In gonorrhoeal ophthalmia drainage is all important, and on the least doubt about the pus getting away freely I would slit the outer canthus; for the rest, I have relied mainly on hourly douching with boric acid lotion and daily painting of the mucous surfaces of the lids with 2 per cent silver nitrate. Throughout the treatment of gonorrhoea and in tests of cure laboratory aid is indispensable, and in this I would include not only microscopic examination of smears, but cultures and the complement fixation test. The question of employing cultures may be difficult when the worker is far removed from a laboratory. It can be partially

solved by drawing the secretion into a capillary pipette and posting this, after sealing the open end of the capillary. In testing for cure, although we may perhaps be not quite in a position to say that a positive complement fixation reaction some weeks after disappearance of all signs means that the patient is certainly still

harbouring gonococci, such a finding is highly suggestive and calls for a repetition of all the other tests, with provocation designed to unearth buried foci. Naturally a steady diminution in the strength of the reaction after the signs have disappeared is valuable support in concluding that the infection has been eradicated.

Reviews

WILHELM CONRAD RÖNTGEN AND THE EARLY HISTORY OF THE RÖNTGEN RAYS.—By O. Glasser. 1933. John Bale, Sons and Danielsson, Ltd., London. Pp. 494. Illustrated. Price, 32s. 6d.

THERE is probably no single scientific event that has had so profound an influence on the conduct of medical practice as the discovery of Roentgen rays; it is therefore fitting that the full details of the discovery, and of the life and work of the discoverer, should be available for the present generation and be preserved for posterity, so that the name of this great pioneer may be duly honoured now and in the future.

That this great discovery was made during the lives of many of us adds to our interest in the subject and must have facilitated the work of the author of the book under review—though it will have limited his scope for imaginative writing—as he had not to translate ancient papyri nor to dig out and interpret forgotten manuscripts, but only to turn up the scientific journals and daily newspapers of forty years ago in order to obtain his facts. Nevertheless, the propinquity of the event has not prevented a number of fables arising, some of which the author has shown not only originated from very unreliable sources but were scientifically impossible, as for example the story of the Hittorf tube having been placed on a book containing a metal key under which was a photographic plate. The true facts appear to have been as follows:—

Röntgen was experimenting with cathode rays from a Crooke's tube, which had been partially surrounded by cardboard, and probably tin foil; on the table was lying a piece of barium platino-cyanide paper. The paper was lying in the shadow of the light-impervious shield of the tube, and Roentgen noticed that it was nevertheless fluorescent.

It was the fact that he immediately noticed and appreciated the significance of this phenomenon, and not the actual accident of the discovery that distinguished Röntgen from other professors of physics in minor universities and from dilettante experimenters with high-tension apparatus and Crooke's and Hittorf's tubes. He at once proceeded to carry out a series of experiments which proved to himself and to the scientific world that the 'rays' he had by chance discovered were not the previously-known cathode rays, nor any form of light rays, but a new kind of ray with powers of penetration varying according to the density of the substance penetrated.

Few scientific discoveries have so rapidly gripped the imagination alike of the lay, the scientific, and the medical public. The possibility of the production of such rays had no doubt entered the minds of physicists, but to the general public the discovery was so sudden, so surprising, and so complete that within a few days of the first announcement details had been telegraphed all over the world, and for a time the subject formed one of the main topics of conversation in all civilized communities. It cannot be said that the full potentialities of the discovery were at once realized, as since this date the advance in our knowledge of Roentgen rays has been continuous; it has been marked by many triumphs and not a few tragedies; and still we feel there are further possibilities.

Otto Glasser's book is a very satisfactory biography; it tells the story of the life of Wilhelm Conrad

Röntgen, it records all the available details of his outstanding discovery, and it gives one an insight into his character. He was not an easy subject for biography, as with the one brilliant exception there are few high lights in his work, life or character for the artist to use. He appears to have been not an outstanding genius but an industrious, thorough, and conscientious investigator; and in his private life a simple and modest man, and a devoted husband. The letters which are reproduced in the chapter of personal reminiscences certainly give one an insight into his character, but in the reviewer's opinion they do not always indicate the qualities which the writer of this chapter suggests.

It is a book that we can thoroughly recommend.

L. E. N.

A SYSTEM OF CLINICAL MEDICINE.—By T. D. Savill, M.D. (Lond.). Edited by A. Savill, M.D., and E. C. Warner, M.D. Ninth Edition. 1933. Edward Arnold and Co., London. Pp. xxx plus 1063. Illustrated. Price, 28s.

THIS system of clinical medicine has certain features that distinguish it from the ordinary system of medicine. The usual methods of arrangement have not been adopted, for example, according to groups of diseases—acute infectious diseases, etc.—but the subject is approached from the clinical point of view. One cannot perhaps do better than give an example:—Chapter XVI is headed 'General debility, pallor, emaciation'; after introductory remarks two pages are devoted to symptomatology and a summary of the clinical examinations that should be made; then there are twelve pages describing the methods of examination of the blood; these descriptions are clear and concise, and for the most part sufficient to allow the student to undertake the examinations himself—but of course many practical details have had to be omitted—and there is a useful plate showing individual blood cells and blood 'pictures'. (We feel that we must interpolate a criticism here; there is no indication on the plate, or on the descriptive page opposite, as to the stain used; that it is obviously a Romanowsky stain, is no excuse in a textbook meant for students. This fault is a common one in textbooks, but we mention it because it is so easily remedied.) The next section is headed 'Diseases which give rise to general debility . . .'; these are classified according to which is the most prominent symptom—anæmia, loss of flesh, or debility; in the anæmia group, pernicious anæmia comes first; this disease is then dealt with in the orthodox way—under the headings symptoms, diagnosis, prognosis, ætiology, etc. Further down in the anæmia classification, under the sub-heading constitutional conditions, syphilis is given, and later in this chapter syphilis is dealt with fully.

Another chapter is headed 'Pyrexia' and in this the causes of pyrexia are classified and discussed. The system necessitates a considerable amount of cross-referencing, but is on the whole very satisfactory. The writers have placed themselves in the position of the physician faced by a patient with certain symptoms, and have consequently produced a book that will be more practically useful to both the undergraduate and the post-graduate student than the ordinary academically-arranged textbook. The different paragraphs have

been revised and in many cases entirely re-written by experts in the various subjects; Lieut.-Col. Byam and Dr. Hamilton Fairley being responsible for those referring to tropical diseases, consequently the mistakes which so often mar textbooks on general medicine have been avoided; any criticism of these sections would be in connection with omissions and for these the writers cannot be held responsible.

The book should have a special appeal in this country as a textbook of medicine; it is very reasonably priced and is in its way complete. We can strongly recommend it to teachers of medicine as a standard textbook to recommend to students.

MATERNAL MORTALITY AND MORBIDITY.—By J. M. Munro Kerr, M.D., F.R.F.P.S., F.C.O.G. 1933. E. and S. Livingstone, Edinburgh. Pp. xviii plus 382. Illustrated with maps, diagrams, charts, skilograms, and hospital plans. [Obtainable from Messrs. Butterworth and Co. (India), Ltd., Publishers, Calcutta.] Price, Rs. 18-12.

PROFESSOR MUNRO KERR'S treatise on 'Maternal Mortality and Morbidity' contains a vast amount of informative material of first class importance in the solution of the problem. The mass of carefully chosen statistics alone is a very valuable contribution and the book will in consequence be a source of reference for all future students of this difficult subject. The statistics have been carefully examined and the conclusions drawn, deserve to be widely known as they come from the keen and critical mind, of one who has had long experience of midwifery, with and without antenatal care, and of various changes in the management of labour.

The first section of the book is a survey of the causes of maternal mortality and morbidity. It deals not only with the antenatal factors but contains some very enlightening tables showing the results of operative practices, still too prevalent in the management of labour; in other words he clarifies the intranatal factor predisposing to death and disablement. Manual removal of the retained or adherent placenta for instance is shown to be one of the most dangerous of obstetric operations and a more extensive use of saline injection by the umbilical vein is recommended. The emphasis laid on anaemia, trauma, fatigue and prolonged labour as contributory factors to the onset of sepsis throws new light on the subject of infection. The influence exercised by them is ample justification for the use of 'low forceps' as advocated by the author. The necessity for meticulous attention to detail in everything connected with the care of the prospective mother is ably set forth and if only the general practitioner would read for himself the facts, a great improvement in the deaths and disablement from childbirth would result. Unfortunately this section of the book is very largely statistical and unlikely to appeal to many outside the ranks of the obstetric and public health experts.

Another feature is the clear presentation of the differences in death registration in different countries. The figures for countries so closely associated as England and Scotland even, are not strictly comparable because of differences in assessing the predominant cause of death where two are certified; the practice of including deaths from criminal abortion amongst deaths from violence; inclusion of deaths from puerperal albuminuria and convulsions sometimes under eclampsia and sometimes under associated diseases which do not appear in statistics of puerperal deaths.

The picture of untoward events in pregnancy and labour would be incomplete without an outline of the more remote effects of these adverse occurrences. In a chapter entitled maternal morbidity and subsequent disablement, Dr. Donald McIntyre has attempted to assess, from the subsequent health of the mother, the end-results of labour both normal and complicated. The section on neonatal death and disablement by Professor G. B. Fleming correlates disease and death

in early infancy with the normality or otherwise of pregnancy and labour. The picture, if well and truly drawn, is gruesome and one turns with hope to the later sections of the book where measures for the prevention and control of these deaths and disasters are set forth.

Antenatal care is the first line of defence and the figures quoted speak for themselves.

The difference in the death rate between the booked and emergency cases needs no explanation. The variation in the Glasgow and London figures is explained by the adequacy of the antenatal care, in the latter it is 'early and adequate', while in the former it is 'late and casual'. A chapter on intranatal care, the second line of defence, is excellent and extremely practical.

Professor Munro Kerr next turns his attention to the services which must be provided if any reduction is to be effected in the present 'unsatisfactory and undiminishing' level of the mortality graph. The differences in the organization and supervision of domiciliary practice, as conducted by midwives attached to the large maternal hospitals, to smaller maternal hospitals and homes, to nursing institutions, and by midwives practising privately and unattached to any institution, is outlined and the outcome of the differences illustrated. The author deprecates private unattached practice, because it practically precludes the use of a sterilized outfit and sterile dressings at the time of confinement. In the service, as conducted by doctors with the midwife acting as assistant, the mortality rate is higher than when a midwife alone is in attendance. Professor Munro Kerr's observations on the subject are interesting; he states quite clearly that the problem of the abnormal in general practice will not be solved, even by taking the specialist into the home. His considered judgment on the future of domiciliary midwifery is given in the form of a summary to the first chapter of part III.

The institutional midwifery service is treated in the same adequate way; the number of beds is estimated and recommendations on the design, organization, staffing and equipment of the hospital are included. Professor Munro Kerr does not quite see eye to eye with the departmental committee on maternal mortality and morbidity on the subject of the future of antenatal clinics provided by the public health authority, and one is inclined to agree with him rather than to accept the verdict of the departmental committee that the day of the clinic is almost run. Transport and the training of medical students in obstetrics complete the survey.

Section IV, one of the chief objects of the work, namely the co-ordination and co-operation of the several factors which go to the making of a complete maternity scheme is set forth. The scheme outlined appears to cover all essentials and to secure continuity in the care and observation of the expectant mother without undue scrapping of existing institutions.

Professor Munro Kerr says that 'the essential factors prejudicial to betterment are permitted to continue—not because we are ignorant of them but because we have not sufficient determination to remove them'. The essential aim of the author is to point the way of removal. The book is the work of an acknowledged authority, and it is difficult to exaggerate its importance to all serious students of the problem of maternal deaths and disablements.

J. M. O.

PULMONARY TUBERCULOSIS IN GENERAL PRACTICE.—By Andrew Morland, M.D., M.R.C.P. 1933. John Bale, Sons and Danielsson, Ltd., London. Pp. ix plus 113. Price, 2s. 6d.

WE congratulate the author, who is resident physician of the Mundesley Sanatorium in England, for the wealth of material he has been able to include in a pocket-monograph of 113 pages. The book is divided into two sections—(I) General, dealing with the pathology, symptoms, signs and diagnosis of lung

tuberculosis, and (II) Treatment, which includes general, symptomatic, surgical and special methods. The views expressed by him are remarkably up to date and correct. More space has justifiably been given to information which is likely to be useful to the general practitioner who comes, as he says, from 'the most important branch of the profession dealing with the individual tuberculosis patient'. The importance of 'after-care' has been acknowledged by devoting a separate chapter to the subject. It is interesting to note that he does not admit the superiority of outdoor occupations connected with farming and gardening, over sedentary office work. There is a good deal of strength in his arguments though some may not agree with him. The importance of studying and dealing with the mental aspect of the patient has been emphasized by writing a separate chapter on the subject. A commendable boldness has been shown in expressing his opinions which, we hope, will be very useful not only to general practitioners but to specialists as well. There are a few printing mistakes which, we hope, will be corrected in the next edition.

A. C. U.

AIDS TO PUBLIC HEALTH.—By W. G. Altchison Robertson, M.D., D.Sc., D.Litt., F.R.C.P.E. Third Edition. 1933. Baillière, Tindall and Cox, London. Pp. viii plus 208. Price, 3s. 6d.

THIS small book is more in the nature of an index with short definitions of matters relating to public health. It may be of use to students going up for public health examinations. The information given is of necessity meagre, and so far as tropical medicine is concerned not entirely correct. Thus under plague it is stated that 'human beings with plague in turn infect *Pulex irritans*, bugs and lice, and so the disease spreads rapidly'. This is a statement not generally acceded to by students of plague. Under malaria also, the suggestion is made that Paris green acts by forming a film on the surface and cuts off the supply of air from the larvæ. Students in India may find it useful for a quick run over but it is not particularly suited for India or tropical needs.

A. D. S.

WORKMEN'S COMPENSATION: ITS MEDICAL ASPECT.—By Sir John Collie, C.M.G., D.L., M.D., J.P., Lieut.-Col., R.A.M.C. 1933. Edward Arnold and Co., London. Pp. vii plus 160. Price, 7s. 6d.

THE compensation of workmen for 'accident' during the course or as a result of occupation is thirty-six years old in England. Like many other enactments of this nature, its apparent initial simplicity is a delusion, and some of the legal, medico-legal, and medical aspects are vague and indeterminate. The words 'by accident' occur in various sections of the Act, but are nowhere defined. It required ultimate appeal to the House of Lords to decide whether rupture occurring to a workman in the course of his duty was 'an accident' in the meaning of the Act. On the other hand mental derangement and suicide have been held to be 'accidents' in the sense of the Act.

In England, medical practitioners, under the National Insurance Act and the Workmen's Compensation Act, may have important relations with their industrial patients and upon their judgment may depend very important issues. Sir John Collie has had a large experience both as medical adviser, consultant and referee in workmen's compensation cases. He gives excellent and detailed advice how to approach such cases and how to conduct their medical examination. In various chapters he discusses the common diseases and disabilities which are the result of accident, and shows how to apportion these diseases to their proper causes, both ordinary and occupational. He has excellent advice for the medical men who willingly or unwillingly may be called on to give evidence in the witness box in workmen's cases. There is a Workmen's Compensation Act in India, but owing to the nature

of the law the ordinary medical practitioner here does not come into such close contact with these cases as in England. Nevertheless, the book will be found of very great interest and is one to be kept in mind for reference by the specialist and the practitioners here who may be called upon to deal with such cases of 'accident'. The book is written very interestingly and there should be a copy in every reference medical library.

A. D. S.

A LABORATORY MANUAL OF PHYSIOLOGICAL CHEMISTRY.—By W. Wright Willson. Second Edition. 1932. The Williams and Wilkins Company, Baltimore. Pp. 284. Price, 12s. 6d. (Agents are: Messrs. Baillière, Tindall and Cox, London—The book is available from them.)

THIS is the revised second edition of the book originally written in joint authorship with Prof. Walter Jones and is chiefly intended as a guide to the students for laboratory work.

As before, the book is divided into two portions, part I, dealing with general chemistry, inorganic and organic, and part II, dealing with body tissues and fluids, including in it, several sections on quantitative analysis of gastric juice, blood, urine, etc.

We are pleased to find that the suggestion we made in our review of the last edition for including an alphabetical index has been accepted by the author and this, we feel sure, will be a great help to the reader.

The book, we have no doubt, will prove to be a useful aid to students in their laboratory work and we would recommend it to them as such.

J. P. B.

THE QUEEN CHARLOTTE'S TEXTBOOK OF OBSTETRICS.—By Alick W. Bourne, Trevor B. Davies, L. Carnac Rivett, L. G. Phillips, G. S. Lane-Roberts, and Leslie H. Williams. Third Edition. J. and A. Churchill, London. Pp. 679, with 301 text figures and 4 coloured plates. Price, 18s.

SINCE its first appearance under a slightly different title in 1927 this book has earned great popularity and a third edition has now appeared. It is written by a team of six members of the staff of Queen Charlotte's Maternity Hospital, and has all the advantages, in the form of authoritative treatment of each branch of the subject, and some of the disadvantages, in the form of slight inco-ordination and lack of balance, of this method of compilation. The layout of the book follows usual lines, successive sections dealing with development and anatomy, pregnancy—normal and abnormal, labour—normal and abnormal, the puerperium—normal and abnormal, obstetric operations, the baby, and miscellaneous subjects. The addition to Queen Charlotte's Hospital of a new isolation block for the treatment of puerperal sepsis has afforded the authors a wealth of experience in the diagnosis and treatment of the conditions grouped under this heading which has been incorporated in the book and makes this section the best survey of puerperal sepsis which we have seen in a textbook. Other welcome points are a full description of Kielland's forceps and an account of the Zondek-Aschheim test for pregnancy.

The chief causes of maternal and early infantile mortality amongst the uneducated masses of India which worry the practitioner are probably anaemia, either exaggerated by or secondary to pregnancy, premature birth, due to anaemia or malaria or a combination of the two, and puerperal sepsis, due to incompetent midwifery by untrained *dhais*, and the effect of anaemia and malaria on maternal resistance. Of these, anaemia has not yet earned its rightful place in textbooks of midwifery as an important, or in India as the most important, disorder associated with pregnancy, and is not mentioned in this book. Recent work has stimulated

interest in this subject and we look forward to a future edition in which it will be given a detailed treatment such as is now given to the toxemias of pregnancy. The management of premature infants is described, though not as fully as the practitioner in India would appreciate. For the chapter on puerperal sepsis we have nothing but untinged praise.

As is inevitable in a compilation by several authors there is some overlapping. Pyelitis is essentially the same disease whether it occurs in pregnancy or the puerperium, but it is here dealt with in three sections of the book; again on page 175 the reader is referred to 'works on medicine' for details of the ketogenic diet in the treatment of this condition, whereas a full description of the rationale of the diet, with diet tables for a week, is given on page 469. While we also agree that a detailed survey of the methods of anaesthesia applicable to obstetrics would require a very long chapter, and that the subject therefore requires condensation, yet we consider that this subject deserves considerably more space than does the vaccination of infants, which receives practically the same. There points, however, are but minor blemishes on an

excellent book which should maintain its place in the first rank of textbooks on midwifery.

Abstracts from Reports

ABSTRACTED FROM AN ENQUIRY INTO CERTAIN PUBLIC HEALTH ASPECTS OF VILLAGE LIFE IN INDIA BY MAJOR-GENERAL SIR JOHN MEGAW, K.C.I.E., K.U.P. I.M.S., DIRECTOR-GENERAL, INDIAN MEDICAL SERVICE (1933)

(The views expressed below are purely personal)

THE report deals with an attempt to make a broad survey of certain aspects of village life which have a bearing on the health of the people. The word survey is hardly appropriate, some of the conditions which are dealt with are constantly changing and some are so elusive that it is only possible to obtain vague impressions of their real nature. Provided that these limitations are fully recognized I think the data which have been collected are of considerable value in defining the problem which has to be tackled by medical and public health workers in India.

The information was obtained by the issue of a questionnaire to a large number of doctors whose dispensaries are situated in typical agricultural villages scattered throughout British India. Every effort was made to ensure that the replies to the list of questions should be unbiased and that they should also be the result of personal enquiries by the doctors. It was found that a good many of the sets of replies had to be rejected because they showed inherent evidence of unreliability. The remaining 571 replies constitute a fairly large supply of random samples from which it is possible to form a general idea of what is really happening in the villages. No claim is made for the correctness of every detail of the data and I hope that those who are impatient with inaccurate statistics will regard the figures as a challenge to them to obtain more reliable information. In the case of several of the items this survey represents the first attempt which has been made to find out the facts.

COMMENTS ON THE FIGURES

Average size of families

The average number of members of each family in the agricultural villages varies from 5 in the Central Provinces and Madras to 6.4 in the Punjab; in all the other provinces it ranges from 5.2 to 5.78, the average for the whole of India being just under 5.5.

Average area of land cultivated

The average area of land per head of the agricultural population ranges from 1.45 bighas in Bengal to 5.27 in the Central Provinces (0.72 to 2.63 acres), but of course

the yield of crops in different parts of the country varies so greatly that the actual area of land which is cultivated conveys little information as to the real income of each family.

Physical condition of the villagers

The figures which deal with the state of nutrition of the villagers are frankly impressionistic but they are not likely to convey an exaggerated idea of the number of people who are poorly or badly nourished; the village doctors are unlikely to have adopted a high scale of standards in this matter and it is probable that the figures would have been even more unfavourable if European doctors had made the estimates. Taking India as a whole the dispensary doctors regard 39 per cent of the people as being well nourished, 41 per cent poorly nourished and 20 per cent as very badly nourished. The most depressing picture is painted by the doctors of Bengal who regard only 22 per cent of the people of the province as being well nourished while 31 per cent are considered to be very badly nourished. It is impossible to express any dogmatic opinion as to the relative influence of insufficient diet and disease on the physical condition of the villagers but it is obvious that diet must play a very important part.

Diet

Enquiries were made as to the average quantities of each important article of diet consumed daily by adults, but the figures were found to be incapable of satisfactory analysis and therefore they have not been included in the tables. There was, on the whole, less evidence than might have been expected of actual shortage of food: in most of the villages three meals a day are said to be more common than two and the quantity of food consumed is usually sufficient to satisfy hunger. Although there are a fair number of reports of insufficiency of food it is the quality of the diet that is at fault rather than the quantity; animal proteins in the form of meat or milk are taken in very small quantities; fruits and vegetables are seriously insufficient in most villages at certain seasons of the year. The amount of milk which is consumed is surprisingly small except in the Punjab where the average works out at 10 ounces daily for each adult. In the U.P. it is 5 ounces, in Bombay 4 ounces and in the other provinces 3 ounces or less. Ghee is consumed in negligible quantities of one-tenth to a third of an ounce except in the Punjab where it is rather over one ounce and the U.P. where it is reported as being just over half an ounce. As

ghive is a very overrated source of vitamins, its shortage is of much less importance than that of fresh milk. Without claiming any great degree of accuracy for the evidence which relates to the diets, the data correspond fairly closely with the impressions of those who have interested themselves in the matter: it is evident that the supply of available proteins, fats and some of the vitamins is seriously inadequate except in a few favoured localities.

The information supplied by the village doctors on the subject of diets is entirely in keeping with the results of the investigations made by Colonel McCay, I.M.S., about 20 years ago in Bengal. Colonel McCay and other observers have found that the Indian school-boy shows a much lower gain in weight than boys of corresponding ages in Europe and they ascribe the difference to the unsuitability of the Indian diets, especially to their deficiency in the body-building proteins.

Alcohol

The information with regard to alcohol suggests that very little is consumed by the average villager. The percentage of the people who take alcohol at all works out at 12.3 for the whole of India. Here again it would be unsafe to attach very great importance to the actual figures but it is obvious that, with the possible exceptions of Assam, Bihar and Orissa and Madras, alcohol does not play an important part in the life of the community as a whole.

Population and food supply

In nearly 40 per cent of the villages it is considered that the population is excessive in relation to the available food supply. In Bihar and Orissa nearly 60 per cent of the villages are said to be over-populated: in Bengal and the Punjab the percentage is about 46. The figures which deal with this question have no statistical value: they merely represent the impressions formed by dispensary doctors whose replies are based on their personal views as to what constitutes a reasonable standard of existence. It is likely that most of the medical men who were engaged in making the survey would be prepared to accept rather low economic standards of life as being adequate for the villages: indeed in many cases in which the food supply was stated to be sufficient there was plenty of evidence in the replies to other questions that this was far from being the case.

Disease incidence in the villages

As is the case with most of the other statistics which are given in the tables the figures of diseases prevalent must be accepted with great reserve. Few of the doctors are in so close touch with the villagers that they can give reliable information with regard to the incidence of each of the diseases which are dealt with. In the cases in which it is possible to check the data against other sources of information it is found that there are many discrepancies in details, but the averages for the whole of India correspond fairly closely. It may therefore be claimed that the figures give a fairly good general idea of the prevalence of certain diseases. In the case of other diseases such as rickets, syphilis, gonorrhoea and tuberculosis nothing short of a detailed survey by trained observers could be relied on to supply accurate data. On the basis of the figures which are available the approximate total number of cases of the following diseases among the whole population of 353 millions would be—

	Millions
Rickets	2½
Night-blindness	3½
Syphilis	5½
Gonorrhoea	7½
Leprosy	4
Tuberculosis of the lungs	1½
Other forms of tuberculosis	5
Insanity	4
Congenital mental defect	3
Blindness	2

Rickets.—Rickets, a disease caused by a deficiency in the diet, appears to be very much more prevalent in Bengal than elsewhere and least common in Assam and the Punjab.

Night-blindness.—This is caused by a different kind of dietetic deficiency: it is reported as being excessively common in the United Provinces and rather uniformly distributed throughout the rest of India except Bombay which is remarkably free from the disease. Here again no inference can be drawn except that two forms of dietetic deficiency are comparatively common in India as a whole.

Syphilis and gonorrhoea.—Appear to be more common than has been usually believed; Bengal and Madras easily head the list. The data suggest that something like 5½ millions of people in India actually show signs of syphilis so that if account be taken of those who have had the disease and have lost all obvious signs, it would probably be well within the mark to assume that 10 to 15 per cent of the inhabitants suffer from syphilis at some time or other during their lifetime. The strikingly low rates of venereal disease in the Punjab are entirely in keeping with impressions based on other sources of information.

Leprosy.—The estimate of 750,000 cases of leprosy in India corresponds fairly closely with the opinions which are based on surveys by experts: it is probably on the low side although it is far higher than the census figures.

Tuberculosis.—Tuberculosis is evidently very widespread throughout the villages of India but is specially serious in Bengal, Madras, the Punjab and Bihar and Orissa. Pulmonary tuberculosis seems to be much more common than extra-pulmonary except in the United Provinces and Bombay. The low incidence in the Central Provinces is remarkable and is perhaps associated with the sparse distribution of the population and with defective means of communication.

Tuberculosis is well known to be exceedingly prevalent in the cities and large towns but little is known as to its incidence in rural areas. The evidence of the dispensary doctors goes to show that the disease is very widely disseminated throughout India. From other sources of information it seems likely that the disease is increasing steadily and rather rapidly. The estimate of just over two million cases of tuberculosis in India as a whole is probably much too low; every large town is known to be very heavily infected, and therefore an estimate which is based solely on the incidence of the disease in the agricultural villages must be unduly favourable.

Tuberculosis is a disease which has very special importance in India for the reasons—(1) it is likely that many villagers have never come in contact with infection and therefore are 'virgin soil' on which the disease is likely to thrive, (2) the infection is being steadily spread from the large towns to the villages, (3) the disease constitutes a reliable index of the standards of life which prevail in countries in which it has become established for long periods of time; it spreads rapidly among ill-nourished and badly housed populations and correspondingly diminishes when the people are well fed, well housed and cleanly in their habits.

Insanity and congenital mental defect.—The figures for insanity and mental deficiency taken together show that these diseases are less common than in western countries, viz, 1.7 per mille against 4 per mille in the United Kingdom. Assam and Bengal show fairly high figures of about 3 per mille. The census figures show only 0.3 per mille cases of insanity; they do not include mental deficiency, but even when allowance is made for this it is evident that the census estimate is much too low and that the present survey is likely to give a much more accurate picture of the true state of affairs.

Blindness.—If the figures given in the survey are accepted as being representative there would be 5.5 cases per mille in India against only 1.5 per mille reported by the official census for 1921. The census figures are

certainly unreliable; in every case in which they have been checked by a detailed investigation they have been found to be far too low. For example in the Nask district it was found that there were thrice as many blind as were shown by the census and in other places similar results were obtained by a careful investigation. It is therefore probable that there are nearly two million blind persons in India though some of these may not be totally blind.

The information which deals with the causes of blindness is rather vague; among 2,750 cases of blindness the causes were stated in 1,620 and were as follows:—cataract 618, glaucoma 258, smallpox 256, trachoma 218, interference by quacks 90, ophthalmia neonatorum 85, conjunctivitis 51, and born blind 44. In the remaining 1,130 cases the causes were not stated. It is surprising that keratomalacia is not mentioned, as this is regarded as an important cause of blindness in southern India. Here again a detailed and accurate survey is badly needed.

Cholera, plague and smallpox.—The chief interest of the figures which deal with these diseases is that they serve as controls for the general reliability of the rest of the information obtained by the enquiry.

The following comparison is of interest in this respect:—

	Survey figures. Yearly averages for 1927-1931.	Official figures for British India. Yearly averages for 1927-1931.
Cholera	.. 260,000	301,936
Plague	.. 31,290	61,600
Smallpox	.. 81,000	79,091

Making due allowance for the errors associated with random sampling it is evident that if the survey were our only source of information as to the prevalence of these diseases the broad general impression would not be seriously misleading. In the case of plague the yearly variations are very great, for example, in 1929 there were 72,489 deaths and in 1930 only 21,841 so that the estimate formed from the survey falls well within the range of yearly variation though it is considerably lower than the average of the past five years. The comparative accuracy of the figures for cholera and smallpox does not justify any claim that the estimates of frequency of such diseases as rickets, syphilis, gonorrhoea, leprosy or tuberculosis are likely to be equally reliable; difficulty of diagnosis, concealment of the diseases and other factors combine to confuse the picture. It is universally recognized that the registration of cases of cholera, plague and smallpox is much more accurate than that of other diseases which are less striking in their manifestations.

Enlargement of the spleen (malaria).—For all practical purposes enlargement of the spleen means malaria except in the localities where kala-azar is common. The cases of enlarged spleen which are due to kala-azar and all other causes are not sufficiently numerous to affect the figures to any serious extent. The incidence of 14.3 per cent of enlarged spleens gives a fairly good idea of the prevalence of malaria, though a more comprehensive and accurate survey is much to be desired. From the figures it appears that the number of persons who suffer every year from malaria in India is not less than 50 millions, and may easily exceed 100 millions in some years.

Age at which cohabitation and child-bearing begin

The figures showing the average ages at which girls begin to cohabit with their husbands and give birth to their first child are the most important and significant of the whole series. In the ordinary course of events girls begin to cohabit at the age of about 14 years and have their first baby at 16. The remarkable uniformity of the estimates of the ages of cohabitation and first pregnancy shows that these figures can be accepted as being reasonably accurate: they indicate that the normal custom is to impose the cares and dangers of motherhood on immature girls at an age when they ought to

be attending school. Considering the early age at which child-bearing begins the average number of children born to each mother is lower than would be expected; it is probable that the young mothers usually become worn out and incapable of having children before they reach the age of 30. The figures showing the average duration of lactation are in accordance with the prevailing impressions on the subject. The prolonged period of lactation imposes a very heavy strain on the vitality of the young mothers.

Conclusions

Taking the results of the collective enquiry as a whole and making the most liberal allowance for error the resultant picture is gloomy to a degree. From the survey and other sources of information it is certain that (1) India has a poorly nourished population, (2) the average span of life is less than half of what it might be, (3) periods of famine or scarcity of food have been occurring in one village out of every five during a ten-year period in which there has been no exceptional failure of the rains, (4) in spite of the excessively high death rate the population is increasing much more rapidly than the output of food and other commodities, (5) young girls who ought to be still at school are forced to become wives and mothers, many of them are doomed to die in child-bearing, (6) epidemics of cholera, plague, and smallpox are commonplace occurrences. Malaria is constantly present throughout the greater part of India, (7) worst of all, there is little evidence that the educated classes of the community have realized the full gravity of the situation: at any rate they have made no constructive proposals for investigating the problem or for working out a plan for its solution.

The history of the past century is that the Government of India has constructed canals, railways and roads, it has provided security of life and property, promoted education, medical relief, improvements in agriculture and industries and instituted measures of public health. The net result is that more than 350 millions of people are living in a better economic condition than was the case when the population was only 250 millions. This is the bright side of the picture but the present situation does not justify a complacent attitude. It is clear that the growth of population has already begun to outstrip the increase in the production of the necessities of life so that even the existing low standards of economic life must inevitably become still lower unless some radical change is brought about. The outlook for the future is gloomy to a degree, not only for the masses of the people who must face an intensified struggle for bare subsistence, but also for the upper classes whose incomes depend on the production of a surplus of crops and other commodities. If the entire produce of the soil is needed to provide for the urgent needs of the cultivators nothing will be left for the payment of rents or revenue, nothing to exchange for other commodities or even for the purchase of railway tickets and the whole social structure of India must inevitably be rudely shaken if not completely destroyed.

The first step should be to make an accurate survey of the present position and a reliable forecast for the future. When this has been done it is certain that the educated sections of the community will be awakened to the necessity for immediate and concerted action if the country is to be saved from disaster. Energetic measures for the prevention of disease are obviously necessary, but these cannot save the situation unless they are accompanied by equally energetic measures for the education of the masses in the principles of life planning. Other peoples have achieved a considerable degree of success in gaining a mastery over their environment and there is no reason why the people of India should not gain a similar or even greater success provided that the problem is tackled in an intelligent manner.

It is easy to point to the present economic crisis in Europe and America and to suggest that this implies the failure of civilization, but it is possible to profit by the failures as well as the successes of others. It is by no means desirable to imitate the example of western countries in a slavish manner: what is needed is that we should work out a policy which is suited to the special needs and conditions of India, and there is *prima facie* evidence that the formation of such a policy is a matter of very great urgency.

ABSTRACT OF THE REPORT OF THE SESSION OF THE OFFICE INTERNATIONAL D'HYGIENE PUBLIQUE HELD IN PARIS, 1ST TO 10TH MAY, 1933. BY LIEUTENANT-COLONEL A. D. STEWART, I.M.S., DIRECTOR, ALL-INDIA INSTITUTE OF HYGIENE AND PUBLIC HEALTH, AND DELEGATE FOR THE GOVERNMENT OF INDIA

As Major-General Graham, Public Health Commissioner with the Government of India, was unable to visit the May meeting of the Session, the Government of India deputed Lieutenant-Colonel Stewart as its delegate. It will be remembered that the Office International d'Hygiene Publique represents the permanent location in Paris of the International Sanitary Convention to which most of the countries of the world are signatory. The object of the convention is to have an international agreement concerning the carriage of disease throughout the world, and particularly to agree on the maximum action that can be taken by one signatory country against another in respect of shipping coming from infected or possibly infected ports of the latter. The convention also deals with the important Haj pilgrimage to Mecca and other neighbouring holy places, and with the sanitary conditions and control of these pilgrimages. The permanent committee of the office meets twice a year in Paris, in May and October, and consists of official delegates from all signatory countries. At these meetings, the permanent committee deals with important matters concerning and relating to the convention, and also with the progress of international knowledge appertaining to infectious and other diseases, particularly to their causation, mode of spread, epidemiology and prevention. The office issues a monthly bulletin which contains many important reports and articles. Owing to this being printed only in French, however, these articles do not obtain the wide circulation and publicity which their quality and importance deserve. The President, Sir George Buchanan, hopes that an English edition of the bulletin may soon be forthcoming. The principal subjects dealt with by the office are cholera, plague, yellow fever, and smallpox—diseases in which India is particularly interested and indeed vitally concerned. India's representation at the biannual meetings of the permanent committee is thus important. For the last 5 years, Major-General J. D. Graham, Public Health Commissioner with the Government of India, has represented the Government of India at the office meetings and his presentation of the work done in India, and the difficulties that confront India in public health progress have led not only to a more sympathetic appreciation and understanding of what may sometimes be thought to be the slow advance of public health in India, but to a very much wider and more generous appreciation of the vast amount of valuable work that has been accomplished in India in pioneer research on tropical disease, and actually in its application. It is thus important that India should have continuous and adequate representation at the meetings of the office.

At the May meeting several matters of interest and importance to India were discussed. Chief amongst these were the questions of (a) the possibility of preparing an 'omnibus' type of agglutinating serum for the cholera vibrio, agglutination with which could be accepted an authentic diagnosis of cholera vibrio, and (b) the vexed question of cholera carriers. Since

the discovery of the El Tor vibrio, and of vibrios of a non-agglutinating character in the stools of the residents in or coming from areas affected either endemically or epidemically with cholera, there has been a great controversy over the question of carriers, and indeed great difficulty both in assessing the correct inferences that should be drawn from finding such atypical vibrios in the stools of contacts, pilgrims and immigrants and travellers, and in deciding the action which it is justifiable to take in such cases. The question was further complicated last year by the finding in Syria and Egypt of agglutinating vibrios in travellers coming from Iraq, not only from neighbourhoods affected with cholera, but from areas absolutely free from cholera. To study these problems the office appointed a cholera committee or commission. They entrusted Dr. Madsen and Dr. Cantacuzene with the preparation of anti-sera; and the vibrios used should satisfy certain strict conditions. Such sera are now being tested in India and elsewhere and the results should be available shortly. On the vexed questions of carriers, Dr. Convy was asked to prepare a statement on the whole question. His paper which was presented to the May meeting is a very complete record of all the work that has been done and all the views that have been held on the cholera carrier question. Indian experience has been at variance with that of workers in Syria and Egypt. Agglutinating healthy carriers have never been found in India, except in one or two isolated and rather unique instances such as that reported by Grieg in 1913. We recommend our readers to read Dr. Convy's report which will be published in the monthly bulletin of the office. In the discussion on these subjects, the valuable work that had already been done in India was noted, and it was realized that only in India could work on cholera be satisfactorily carried out and the meeting of the office passed a resolution to the effect that it hoped it would be found possible for the Government of India to form a specific inquiry or commission on cholera, which would embrace the subjects of the preparation of specific anti-sera and the carrier question. A great deal of interesting work on cholera is at present being done on cholera both under the auspices of the Indian Research Fund Association and by the School of Tropical Medicine, and the subject is one which will probably be fully discussed at the research workers' conference at Calcutta in November and December.

The subject of plague, and the disinfection and deratization of ships was another subject of importance to India discussed. The International Sanitary Convention of 1926 only permits of one deratization at the expense of the ship and suggests that only under very exceptional circumstances should two fumigations be carried out. It is now realized that special circumstances may exist rendering a preliminary fumigation with loaded holds necessary, followed by a second fumigation after or during discharge, if plague or live rats are found after the first fumigation. An amendment to make this point clear has been proposed and will be forwarded to signatory countries. Interesting papers on the procedure and standards for fumigation by SO₂ were submitted and have been published in the bulletin.

Readers will remember that the Government of India insisted on such an interpretation of the new International Aerial Traffic Convention, that it should reserve the right of prohibition of air traffic coming from countries infected with yellow fever, for reasons which it might itself deem sufficient. The new aerial convention with this interpretation has now been drafted and is ready for signature by the various countries, indeed it has already been signed by several. An interesting communication was given by Dr. Findlay on the methods of immunization against yellow fever by methods based on those of the Rockefeller workers. A variety of other subjects were discussed at the May session and the salient features of these have been summarized by Colonel Stewart in his report. In summing up his impressions of the meeting, Colonel

Stewart states 'The research work in India is highly appreciated, but I gathered that in the field of everyday sanitation, there is an impression that not enough headway is being made, though the difficulties in the path of progress in this direction are understood'.

Everyone interested in research and medicine and public health work in India owes a great deal to Major-General Graham who will soon retire from the post of Public Health Commissioner with the Government of India. General Graham has been successful in presenting the position and the work done in India at the office for many years and his services in this connection will be very much missed.

ABSTRACT OF THE ANNUAL REPORT OF THE EXECUTIVE HEALTH OFFICER OF THE CITY OF BOMBAY, 1932

The Health Reports of Indian towns are always of interest. Advancement in environmental sanitation, water supplies, and drainage, for instance, should be possible in towns where collective funds and administrative and executive staff are available. The progress made annually in this direction in Indian cities and towns is usually disappointing. This year's report on Bombay is more hopeful. We draw attention to some of the more interesting points.

The population according to the 1931 census was 1,161,383. This was a 1.23 per cent decrease in place of a 20 per cent increase during the decade of 1911-20. The 1931 census figure was the result of trade and other depression in the city at the time of the census operations and is not a permanent loss to the city population. The death rate for 1932 was 19.7 per 1,000—the lowest for the last 50 years. This is an uncorrected rate but it is unlikely that there has been much of a decrease of numbers in the poorer classes, amongst whom the death rate is ordinarily high. It is likely that the year 1932 was a healthy one. When we turn to the mortality, we find that the mortality from cholera, smallpox, and plague was practically nil. There was also little or no mortality from influenza. The mortality in 1932 therefore represented what is normally happening in the absence of epidemic disease. Turning to the causes of death, we find that the only considerable mortalities are those due to respiratory diseases (excluding tuberculosis), congenital debility and diseases of early infancy, malaria, and tuberculosis. The deaths from respiratory diseases require further investigation. Tuberculosis causes 12 deaths per 1,000—not by any means as high as in many other towns in India and in other oriental towns. There are 2 tuberculosis dispensaries and a sanatorium with 32 beds. Advanced cases of phthisis are taken into the Maratha Hospital, where there are 80 beds for this purpose.

The chapter on malaria is always interesting in view of the reports of Bentley and Covell. Mahim and Worli wards show spleen rates of 22 and 23, the Market ward one of over 10. The other wards vary from 1.3 to 5. Work on filling in wells, mosquito proofing and closure of wells is progressing. Houses and buildings are systematically inspected for constructive and other defects leading to mosquito breeding and are dealt with summarily.

The birth rate was 24.8 per 1,000. This is almost certainly an under-estimation. The season of lowest birth rate is in the central months of the year, the highest rate occurring in November, December and January. (The mortality, on the other hand, hardly varied from month to month in 1932, though it was lowest in June and July.) During the last 5 years there has been a remarkable fall in the infant mortality rate; the 1932 rate was 218, and cutting out certain deaths in unregistered births the figure would be 191. We have on previous occasions commented on the well-organized maternity- and child-welfare work in Bombay. Municipal district nurses do excellent work in the houses and there are now 5 maternity homes maintained by the municipality.

With regard to the general sanitary state of the city, the city as a whole is now supplied with an adequate quantity of pure water from Lake Tansa. The whole supply is chlorinated, but there is no filtration.

The drainage and sewage problem does not seem to have progressed much since last year. Some new sewers are being constructed, to be used when the location of the outfall has been decided. In the meantime, the situation has been much aggravated by the increased water supply and the erection of new buildings.

The basket privies, well known as disgusting nuisances to all who have ever entered the back lanes of Bombay, are gradually but surely being reduced in number and replaced by water closets. During 1932, 2,651 privy seats were converted; the number of seats remaining to be converted in the sewered areas is about 12,000.

Housing.—Houses are regularly inspected and defects remedied under the various sections of the Municipal Act.

The appendix to the Report contains the Report on the Arthur Road Hospital for Infectious Diseases, the Maratha Hospital, the Municipal Laboratory and the Superintendent of Vaccination.

ABSTRACT OF THE QUARTERLY REPORT OF THE MYSORE DEPARTMENT OF PUBLIC HEALTH, NOS. IV AND V, FROM OCTOBER 1932 TO MARCH 1933

These reports give a running comment on the work carried out in Mysore State every quarter. They are therefore mainly statements of numbers and figures of various kinds, and résumés of progress in certain works. Malaria surveys are being carried out in various parts of the State. Water supplies and conservancy systems are being improved. The construction of bored-hole latrines seems to be progressing very favourably. We read that during the last Mysore Teachers' Conference held at the national high school, Bangalore, 6 bored-hole latrines were put up for the use of the delegates—good educational propaganda. An opinion after a few years' working on this form of latrine would be informative, as many claims have been put forward for its being the solution of village conservancy. These reports should be very useful to the various organizations in Mysore State and we trust they are well distributed and read.

ABSTRACT OF THE REPORT ON THE BURMA FOOD AND DRUGS ACT, 1928, WITH RECOMMENDATIONS FOR FOOD STANDARDS. BY EDWIN H. BUNCE, F.I.C., F.C.S., PUBLIC ANALYST TO THE GOVERNMENT OF BURMA

The Government of Burma in 1928 passed a Food and Drugs Act, which however could not be put into action until rules laying down standards and definitions were passed and until a public analyst or analysts were appointed. Mr. Bunce was appointed public analyst in 1930 and has since his appointment assiduously worked at analysing food-stuffs in Burma. Sufficient has now been done in this direction to enable Mr. Bunce to recommend food standards for official adoption and at the same time to recommend some amendments to the Act passed by the Burma Legislature in 1928. The report will be found of considerable interest to other provinces in India, both to those which have already passed food adulteration acts and drawn up food standards and to others which have one or other of these actions under contemplation.

Mr. Bunce favours English procedure, whereby general definitions only are given, and it is left to the public analyst to report to the court whether a substance is genuine or not; in the latter case giving the nature of the adulteration, and the percentage of foreign substances present. There is much to be said for this view as, when definite standards are laid down, samples may be found showing unquestionable adulteration, but which nevertheless conform to the

limits of the official standards. In such cases complications arise and the presence of the analyst would be necessary in court in order to explain such an apparent discrepancy.

The following are the conclusions and recommendations for standards in Burma arrived at by Mr. Bunce.

Cow's milk.—This should not contain less than 3.0 per cent of milk fat, or less than 8.5 per cent of milk solids other than fat.

Buffalo's milk.—5.0 per cent milk fat and 9.0 per cent non-fatty solids are the figures recommended. In most Indian provinces 3.5 and 6 per cent of fat are the figures for cow's and buffalo's milk.

Condensed milk.—The English Regulations of forms and schedules are followed in Mr. Bunce's recommendations.

His figures are as follows:—

Condensed milk	Percentage of milk fat	Percentage of total solids
1. Full cream, unsweetened	9.0	31.0
2. Full cream, sweetened ..	9.0	31.0
3. Skimmed, sweetened	26.0

These are minimal percentages.

Dried milk.—Mr. Bunce wisely recommended having only 1 description, viz, Dried Full Cream Milk. It should contain not less than 26 per cent of milk fat.

Ghi.—No differentiation is made between cow and buffalo and mixed ghi. The standards for ghi are:—

Reichert-Wolly figure minimum of 24.

Butyro-refractometer reading between 40° and 43° at 40°C. Butter a maximal limit of 16 per cent of water is recommended. No standards (wisely, we think) are suggested for the various edible oils.

Tea, coffee, and chicory are defined only in general terms for the reasons already given.

An appendix gives the result of Mr. Bunce's analytical result in respect of milk and butter. The report should be read by all public analysts in India and by those assisting in preparing draft food adulteration acts and rules.

ABSTRACT OF THE THIRTEENTH ANNUAL REPORT OF THE BLIND RELIEF ASSOCIATION, BIJAPUR, 1932

THE twelfth annual report of this organization was noted in our issue of February last, and the report under review is a record of another year of useful work throughout ten areas of Bijapur district and Akalkot State, but work in three other neighbouring states had to be discontinued on account of lack of funds mainly caused by the cessation of grants to the association from these three States.

Copies of this report and information regarding the association can be obtained from the Civil Surgeon, Bijapur, who is its chairman. Donations towards the association's funds may also be sent to the same address.

ABSTRACT OF THE ANNUAL REPORT, 1932, OF THE SUDAN MEDICAL SERVICE

THE Sudan must almost be unique in tropical provinces in that it contains practically every known tropical disease except cholera. Malaria, black-water fever, bilharziasis, guinea-worm, hydatid disease, kala-azar, leprosy, sleeping sickness, yaws, relapsing fever are all prevalent, while typhoid fever, tuberculosis, cerebro-spinal meningitis, diphtheria, and influenza are also problems.

The chapter on staff and organization would have been more helpfully placed at the beginning than at the end of the report. The Sudan Medical Service combines medical and public health work and the administrative staff look after both aspects—a wise combination. The

staff of the Syrian medical officers are gradually being replaced by Sudanese medical officers trained in Khartoum. The subordinate Sudanese staff consists of dispensary hakims, sanitary hakims, and sanitary barbers, sheikhs' dressers and chiefs' dressers.

The following are some of the interesting points in the report. Great importance is attached to the preservation of health of the officials. The loss of work by sickness in 1932 is worked out at 5.9 officials compared with 16.0 in 1929.

Bilharziasis.—This is mildly endemic over a large area. The preventive work instituted consists of the establishment of bored-hole latrines close to the canals, and near villages, and the gradual installation of such latrines in individual huts in villages. The square deep pit latrine however seems to be giving more satisfactory results than the bored-hole latrine. The natural history and bionomics of the snail responsible for infection have been worked out and the knowledge obtained applied to their destruction.

Systematic treatment of infected persons is undertaken on a large scale.

Kala-azar is endemic in the Sudan along the Blue Nile as it emerges from Abyssinia into the Sudan. The incidence becomes smaller as the distance from the Abyssinian border increases.

A leprosy survey is being carried out and knowledge of the incidence of the disease is being acquired. Where the staple food is milk, the disease seems to be less prominent. Where cattle cannot survive in the 'fly country' the incidence of leprosy is very heavy indeed.

Malaria increases with the rise of the river Nile and decreases with its fall. Heavy rains in the autumn months produce epidemics.

Sleeping sickness.—New foci continue to appear. The flies lurk near springs, and visits to such springs lead to infection. Such springs are protected by thorn barriers to prevent access. There is danger that infection in the Sudan may spread by refugees coming from trans-border infected areas and stringent measures to prevent this have to be enforced. Several provinces, e.g., Mongalla, have been cleared and kept clear by such measures, despite the fact that they border on infected countries.

Yaws has been very successfully treated with novarsenobillon and the incidence greatly reduced.

Syphilis appears to be widespread however. It is curious that in Khartoum syphilis of the central nervous system is as common as it is in Europe, whereas in the provinces this is not so.

Tuberculosis is a very definite problem, especially in the Southern Sudan where large sections of the population have only recently been brought into contact with the outside world. The disease is the subject of increasing investigation and a large proportion of the population is being tested by the Mantoux test.

Ophthalmology.—A report is given of a rather mysterious outbreak of blindness in certain tribes. The condition is one of retino-choroiditis followed by optic atrophy. The cases appear not to be retinitis pigmentosa, although a familial history is given in some cases.

Medical work.—Mobile hospitals are urgently required, the policy at present pursued is the establishment of a network of dispensaries throughout the province, especially in sleeping-sickness areas. Excellent medical work is carried out by medical missions. Medical training is given at the Kitchener School of Medicine at Khartoum and about 10 new students are annually admitted. There are also a Midwifery Training School and a Nurses' Training School at Omdurman. Work in this province must be full of interest and the report testifies to the interest taken by the medical service in its many-sided work and to a large amount of excellent and conscientious work done both in administration and executive work.

INTRAVENOUS GLUCOSE IN PNEUMONIA AND OTHER TOXÆMIC CONDITIONS LIKE ECLAMPSIA AND SUTIKA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I recently treated two cases of pneumonia by intravenous injection of ten c.cm. of 12.5 per cent glucose solution and from the results I am led to believe that glucose given intravenously on the 4th or 5th day averts the crisis of pneumonia, probably by neutralizing the toxin liberated by the pneumococcus. In both the cases the fever came down by lysis and took about fourteen days to reach normal. In another case, treated at the same time, in which glucose was not given fever came down by crisis on the 7th day accompanied by profuse perspiration and purging.

I have also tried glucose by the intravenous route in *sutika* and I have had gratifying results in almost every case, and the same treatment has given good results in eclampsia in combination with morphine and atropine injections.

Sutika is a Bengali term used for the complicated puerperal complaint characterized by alternate constipation and diarrhoea, loss of appetite and loss of weight, occasionally accompanied by low fever. It appears to be purely a puerperal complaint due to some unknown toxin.

Yours, etc.,
CHINTA HARAN GHOSE,
L.M.P., L.T.M.

KASRA,
30th July, 1933.

PHYRYNODERMA: A CONDITION DUE TO VITAMIN DEFICIENCY

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I have seen to-day a copy of the *Archives of Dermatology and Syphilology* of November 1933. On page 700 there is a paper by L. J. A. Loewenthal on 'A New Cutaneous Manifestation of Vitamin-A Deficiency'. The description suggests that he is probably referring to a condition the same as, or very similar to, that described by me in a paper that I forwarded to you on 16th September last. If you have not yet published this paper, I trust that you will give the date of receipt of my typescript. I proposed the name 'phrynoderma'; Dr. Loewenthal suggests no name for the manifestation he describes. Apparently, Dr. A. Pillai described a similar condition from China in 1929.

I am not particularly anxious over the question of priority, because obviously their papers appeared first, but I would like the date of the receipt of my paper to be mentioned, as it will show that I could not have been aware of this paper by Dr. Loewenthal when I wrote my paper.

Yours, etc.,
LUCIUS NICHOLLS.

BACTERIOLOGICAL INSTITUTE,
COLOMBO, CEYLON,
18th December, 1933.

[Note.—Dr. Nicholls' paper was received by us on 21st September, 1933, and was published in our December issue, page 681.—EDITOR, I. M. G.]

Service Notes

APPOINTMENTS

ON return from leave, Major-General Sir Robert McCarrison, Kt., C.I.E., K.H.P., an officer of the Medical Research Department, is placed on foreign service under

the Indian Research Fund Association, with effect from the 9th December, 1933, for appointment as Director, Nutritional Research.

Lieutenant-Colonel R. E. Wright, C.I.E., Professor of Ophthalmology, Medical College, Madras, and Medical Superintendent, Government Ophthalmic Hospital, Madras, is appointed to officiate as Surgeon-General with the Government of Madras, with effect from the afternoon of 11th October, 1933, until further orders.

On return from leave Lieutenant-Colonel G. Covell is placed on foreign service under the Indian Research Fund Association for appointment as Assistant Director, Malaria Survey of India, Kasauli, with effect from the 14th October, 1933.

Lieutenant-Colonel E. W. O'G. Kirwan, on return from leave ex-India, is re-appointed as Professor of Ophthalmic Surgery, Medical College, and Ophthalmic Surgeon, Medical College Hospitals, Calcutta.

Captain M. L. Aluja and Captain S. M. K. Mallick are appointed substantively to the Medical Research Department, with effect from the 7th March, 1933, and the 1st April, 1933, respectively.

Major W. J. Webster, M.C., Officiating First Assistant Director, King Institute, Guindy, Madras, is appointed as a Supernumerary Officer at that Institute until further orders, with effect from the date on which he is relieved of his present duties.

Captain J. C. Drummond, whose services have been re-placed temporarily at the disposal of the Government of Bengal, is re-appointed to do general duty at the Medical College Hospitals, Calcutta, with effect from the 26th September, 1933.

APPOINTMENTS AND TRANSFERS

The services of Brevet-Colonel J. McPherson, K.H.S., an Agency Surgeon, are re-placed at the disposal of His Excellency the Commander-in-Chief in India, with effect from the forenoon of the 16th October, 1933.

Lieutenant-Colonel J. B. Hance, O.B.E., an Agency Surgeon, on return from leave, is posted as Residency Surgeon in Mysore, with effect from the forenoon of the 16th October, 1933.

The unexpired portion of his leave is hereby cancelled.

Lieutenant-Colonel J. A. S. Phillips, Director of Public Health, Bihar and Orissa, is appointed to officiate as Inspector-General of Civil Hospitals, Bihar and Orissa, in addition to his own duties, with effect from the 24th October, 1933, until further orders.

The services of Major N. B. Mehta are placed temporarily at the disposal of the Government of Bengal, with effect from the 7th October, 1933, for employment in the Bengal Jail Department.

The services of Captain H. S. Waters are re-placed temporarily at the disposal of the Government of Bombay, with effect from the 10th October, 1933.

The services of Captain J. C. Drummond are re-placed temporarily at the disposal of the Government of Bengal, with effect from the date on which he resumed charge of his civil duties.

Lieutenant F. W. Whiteman, I.M.S., is restored to the establishment, 18th October, 1933.

LEAVE

Major-General J. D. Graham, C.B., C.I.E., K.H.S., Public Health Commissioner with the Government of India, is granted with effect from the 11th December, 1933, leave on average pay for 1 month and 22 days combined with leave on half average pay for 26 days preparatory to retirement.

PROMOTIONS

Lieutenant to be Captain

Jeremiah O'Neill. Dated 23rd October, 1933.

Lieutenant to be Captain (Provl.)

G. W. Miller. Dated 4th August, 1933.

The seniority of Lieutenant F. W. Whiteman is ante-dated to the 18th October, 1932.

Notes

A NEW SURGICAL INSTRUMENT TRAY

THE new instrument tray illustrated below possesses several advantages over the ordinary type. It is made of best white porcelain, size 16 ins. \times 12 ins. \times 2½ ins., with rounded corners and sloping sides, and is thus easily washed and sterilized. Moulded partitions divide the tray into five compartments, so that instruments may be kept separate, the smaller divisions being particularly useful for surgical needles. In the event of the disinfecting solution being cloudy, the instruments required can easily be found, as the sloping sides cause them to roll to the centre of the compartment, thus

obviating the necessity of groping all over the dish as would be the case with the ordinary type.

Further, the separate compartments enable the tray to be used for both wet and dry dressings.

It can be strongly recommended to the profession as an excellent small instrument and dressing tray for general clinical work. The sunk handles allow of easy and safe carrying.

The tray is manufactured by C. J. Hewlett and Son, Ltd., surgical instrument makers, 35-42, Charlotte Street, London, E.C. 2.

THEELIN AND THEELOL. PARKE, DAVIS AND CO.

THEELIN

THEELIN is the ovarian follicular hormone in pure crystalline form. The ovarian follicular hormone has been demonstrated in the follicular fluid of the ovaries, in the placenta, in the amniotic fluid, and in the blood and urine of pregnant animals and women. The isolation of crystalline Theelin is a most noteworthy step in the development of our knowledge of ovarian physiology and ovarian organotherapy. The credit for this achievement belongs to Dr. E. A. Doisy, Professor of Biochemistry at St. Louis University.

Theelin is manufactured and distributed solely by Parke, Davis and Co., under license from St. Louis University, and each lot of the product is tested and approved by the Biochemical Laboratory of St. Louis University before being released for sale. It is standardized according to the Doisy method (modification of Allen-Doisy procedure), its potency being expressed in terms of rat units. A rat unit is the amount of hormone necessary to induce estrus with cornification, as judged by vaginal smears, in an ovariectomized sexually-mature rat.

Therapeutic indications

Theelin has been subjected to clinical trial in a great variety of conditions characterized by disturbance of uterine or ovarian function, following the lines suggested by the fact that the ovarian follicular hormone is produced in great abundance during the early months of pregnancy and may therefore be regarded as supplying a much-needed stimulus to the reproductive system. As a result of this investigation it has been learned

that Theelin is of particular value in disorders due to the natural menopause-vasomotor disturbances evidenced by headache, hot flushes, insomnia, emotional instability, etc.

A related condition is functional amenorrhea, either primary or secondary. Theelin has proved very satisfactory in both types, but especially in the secondary type, some incidental derangement having interfered with the regularity of the periods. Other disturbances of the sexual cycle, such as oligomenorrhea, dysmenorrhea, and menorrhagia, are amenable in selected cases to the action of Theelin.

Theelin is administered by intramuscular injection, since it is only feebly active when given orally; it is supplied in boxes of six ampoules of 1 c.cm. each, and also in boxes of six vaginal suppositories.

THEELOL

Theelol is similar to Theelin in estrogenic activity, but is distinctive in that it is effective on oral administration. The practical importance of this new hormone, which offers a means of stimulating estrogenic activity and at the same time does not necessitate hypodermic injection, will at once be apparent to the clinician.

Theelol is available in only one form—Kapseals (sealed capsules) for oral administration, and is put up in bottles of 20 Kapseals, each containing 50 rat units.

Literature on the above products is available from Messrs. Parke, Davis and Co., P. O. Box No. 88, Bombay.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

ABDOMINAL PREGNANCY SECONDARY TO TUBAL GESTATION AT TERM

By M. M. CRUICKSHANK, M.Sc., M.B., Ch.M.
MAJOR, I.M.S.

Superintendent, Government Hospital, Tanjore

and

S. T. ACHAR, M.B.B.S.

Honorary Lady Assistant Surgeon, Government Hospital, Tanjore

A HINDU woman, age 22 years, was admitted into the Government Headquarter Hospital, Tanjore, on the 11th May, 1933, with a history suggestive of malarial fever.

Condition on admission.—The patient was eight months pregnant (third pregnancy), anæmic, with some œdema of the legs, a slight degree of myocarditis, and a blood pressure of 120 mm. of Hg.; her urine was loaded with albumin; and there were scattered râles over both lungs posteriorly.

Height of uterus—thirty-four weeks. Condition of uterus—not acting. Position of fœtus—oblique, head in the right lumbar area. Fœtal heart—136. Vaginal examination not carried out.

After treatment with magnesium sulphate, diuretics and digitalis, the blood pressure fell to 106, and the œdema cleared up. The temperature remained normal during the patient's stay in hospital. An attempt at external version failed. The patient, having improved, left the hospital on the 30th May, against advice.

She was readmitted at 8 p.m. on the 16th June, giving a history of having had labour pains during the previous twenty-four hours and of continuous vomiting. Her urine contained a trace of albumin and there was some slight œdema of the ankles. Her blood pressure was 100, pulse 120, and temperature 101.2°F.

Abdominal palpation.—Fœtal limbs and head very readily felt beneath the abdominal wall, suggesting a ruptured uterus. Fœtal heart not audible.

Vaginal examination.—The cervix was soft; the os admitted one finger; pieces of fleshy tissue could be felt, suggestive of a decidua cast; and the examining finger was blood-stained. The uterus was the size of an eight-weeks' pregnancy.

A provisional diagnosis of secondary abdominal pregnancy was made and the patient prepared for immediate operation.

Operation.—Abdominal section was performed under chloroform anaesthesia. With the incision of the parietal peritoneum the gestation sac was opened and meconium-stained liquor amnii escaped. A living child was removed and the cord severed between a pair of Kocher's forceps. The child, a female, weighed five pounds and showed no signs of any abnormality.

The placenta, within a thin gestation sac, lay in the left lower abdominal quadrant. The sac was but lightly adherent to the large intestine and was readily removed. It is of importance to note here that the placenta was not adherent, in the ordinary sense of the word, to any structure, but was apparently contained in a sac, which was readily removed.

The sac which contained the placenta arose from the middle third of the right Fallopian tube as a thick rounded pedicle, which was clamped, transfixed, and ligated with silk. The fimbriated and uterine ends of the tube were distinctly made out. Later, a probe was passed along the tube from either end, and we consider that the tube had remained potentially patent, being occluded merely by the pressure of the amniotic sac.

The uterus, which was now seen to be the size of that of an eight weeks' pregnancy, was displaced to the left. Both broad ligaments were defined and their relations found unaltered. The left ovary and tube were healthy, the right ovary was not seen. The abdomen was closed with drainage and a pint of glucose saline left in the peritoneal cavity. Though the child did well, the mother gradually sank and was removed from hospital by her relations on the 10th June.

There are several interesting features in this case:—

(a) The youth of the patient.

(b) No prolonged period of sterility preceded the extra-uterine gestation.

(c) Delivery of a full term, living and normal child.

(d) The formation of a gestation sac.

The question which requires answering in these cases is 'what tissues actually form the gestation sac?'

In our opinion what has happened in this case is that the fertilized ovum has become embedded in the maternal tissues of the tube either between the mucosa and the muscular layers or between the muscular layers themselves. The ovum has then developed in the wall of the tube external to its lumen, the tissues of the tube proper forming the gestation sac.

In intra-uterine pregnancy the embedding of the ovum is not deep, penetration never extending beyond the mucous membrane into the muscle, indeed it does not reach very deeply into the mucosa (Eden and Lockyer). The more superficial than the embedding of the ovum in the tube, the greater the similarity to a uterine pregnancy. When the ovum is embedded in the mucosa of the tube a true decidua vera is not formed, the mucosa being deficient in stroma cells. On the other hand should the ovum become embedded between the muscle layers a more marked decidual reaction occurs with an attempt to form a decidua vera. In such a case, as in uterine pregnancy, with the expansion of the amniotic sac, the decidua capsularis and the decidua vera come into contact and these layers, as do also the villi of the corresponding layer of the chorion beneath the decidua capsularis, atrophy and the thinned-out chorion lœve remains.

It is stated that the ability of the Fallopian tube to continue to accommodate the growing embryo till full term is uncertain, but cases are on record where this has occurred.

In such cases, if the tube does not rupture, then the placental chorion escapes injury, and even should the tube rupture the placental chorion may escape injury, provided that the amnion and the chorion lœve have remained intact. If the tube ruptures into the peritoneal cavity, the amnion remaining intact so that the fœtus may continue to live, the placenta grows out through the rent and gains attachment to neighbouring organs and peritoneal surfaces; a layer of lymph forms on the exposed amnion,

forming a secondary gestation sac and a so-called tubo-ovarian pregnancy. Similarly, as in the case of the placenta, this secondary gestation sac becomes closely adherent to neighbouring structures. In this intraperitoneal variety the placenta is usually found lying below the foetus.

It is well known that in these cases removal of the placenta and sac may be attended with severe hæmorrhage and the method of dealing with these placenta constitutes one of the problems of surgery.

The case recorded was one of the intraperitoneal variety, but one in which we consider that there was no rupture of the tube, with therefore no consequent outgrowing of the placenta. This is evidenced by the fact that the sac, a primary gestation sac, and the placenta formed no adhesions to neighbouring organs or peritoneal surfaces, and were readily removed from the part of the large gut to which there was the semblance of an adhesion; this was due to the fact that non-inflamed peritoneal surfaces were in contact.

To prove that the Fallopian tube had not ruptured, a microscopic section of the gestation sac should show, from within outward, peritoneum, muscularis mucosæ of tube, perhaps some decidual cells with atrophic trophoblastic villi, atrophic chorion, the chorion lœve of the anatomists, and amnion. Pieces of the gestation sac in this case were sent to the pathologist, Madras Medical College, who very kindly made sections and sent us the following report:

'Section shows the fibrous wall of a cyst, which is lined internally by a bluish-staining granular material in which nuclei are not seen'. The microscope, then, does not help us to prove that the Fallopian tube remained intact in this case.

In studying these cases it is very necessary to have in one's mind a classification of the primary and secondary terminations of ectopic pregnancy. Schumann's classification seems the most comprehensive and useful (*Gynecological and Obstetrical Monographs*, Vol. VII, 1931).

(1) Primary terminations

1. Resorption of the ovum.
2. Death of the embryo with the formation of a tubal mole.
3. Tubal abortion.
4. Rupture of the pregnant tube into (a) the peritoneal cavity, or (b) the broad ligament.
5. Growth and development of the foetus to full term while still confined within the tube.
6. Interstitial pregnancy, which may terminate by the growth of the foetus into the uterine cavity, the placenta remaining attached to the original site.

(2) Secondary terminations

Tubal rupture, or less commonly tubal abortion, may be succeeded by one of the following:

1. Tubo-abdominal pregnancy, the placenta remaining attached to the tube, the foetus being free in the abdomen—a rare condition.
2. Secondary abdominal pregnancy, the entire ovum being expelled into the abdominal cavity.
3. Tubo-ovarian pregnancy.
4. Intra-ligamentary pregnancy.
5. Ovario-abdominal pregnancy.
6. Abdominal pregnancy secondary to ovarian pregnancy; theoretically possible just as an abdominal pregnancy may be secondary to a tubal rupture.

Werth has demonstrated that cases reported as primary abdominal pregnancies, where the ovum has been fecundated while free in the abdominal cavity and become implanted on any tissue with which it has come in contact—a theoretical possibility, are in reality of tubal origin.

Litzenberg (*American Journ. Obst. and Gynec.*, 1920, I, 223) states that it is impossible for an ovum to implant itself primarily upon the peritoneum. The case described then may be considered as one of primary extra-uterine pregnancy, nidation proceeding at the point of first arrest, its termination being primary and falling under group 5.

As already stated, the question at issue is, 'Is it possible for a tubal pregnancy to go to full term and remain in the tube without rupturing any one of the layers forming the tube?' Opinions as to this point are very vague as a reference to one or two cases in the literature will show.

Conaway (*Trans. Philadelphia Obst. Soc.*, 1911-13) reports a case, where the ovisac, which consisted of the right tube, bore the same relations to uterus and ovary and broad ligament, as a hydrosalpinx. The tube contained a perfectly formed, dead foetus, weight four pounds, and two quarts of slightly greenish fluid. The placenta was attached to the posterior surface of the sac and lay between the layers of the broad ligament. The placental vessels were thrombosed; the ovisac was thin and was ruptured while freeing it from the parietal peritoneum. Schumann places this case in group (1) 5.

Horsley (*Surg. Gynec. Obst.*, 1913-17, 58) describes a case where the child was found lying in the left side of the abdomen among the intestines, covered only by a thin membrane, which also surrounded the placenta. The placenta and sac had a distinct pedicle, which arose from the left broad ligament. A few adhesions of the sac to the intestines and the omentum were readily separated. Considering that the placenta was surrounded by the thin membrane, which formed the sac, and was but

lightly adherent to gut and omentum, this case might be grouped under (1) 5.

Summerville and Thomas (*Internat. Journ. Med. and Surg.*, 1932, XLV, 550), describing a case of eleven-months' abdominal pregnancy, state that, though every physiologic process occurring in normal uterine pregnancy is repeated, every element is pathologic, as the ovum is embedded in tissue anatomically unfit for its implantation and development. Because of its greater thickness, the uterine stroma and mucosa are able to form a decidua that can harbour the ovum and simultaneously protect the uterine musculature from the corrosive action of the trophoblast. In the tube the stroma is scanty and, although scattered groups of decidual cells may be found, there is no true decidua. Attempts are made by the tube to form a decidua capsularis and basalis, but the tissue formed is weak and easily ruptured by the invasion of the trophoblastic villi. The ovum is then set free in the lumen of the tube with hæmorrhage consequent to the rupture of the internal ovum capsule. Here the ovum may cease to live, or it may retain its placental attachment and continue to develop. If it is expelled from the tube into the abdominal cavity and continues to develop it becomes a secondary abdominal pregnancy, with a spread of the placental area over contiguous surfaces of broad ligament or adjacent pelvic organs.

Commenting on their case, in which the child, amniotic sac and placenta were apparently normal, Summerville and Thomas are of the opinion that what happened was probably a slow erosion and gradual rupture of the tubal wall without excessive hæmorrhage, which if severe would have produced fulminating symptoms, the placenta retaining its original implantation with a spread to adjacent structures thus permitting gestation to proceed within the abdominal cavity.

Hellier (*Journ. Obst. and Gynec. Brit. Emp.*, 1924, XXXI, 66-67) describes a case of secondary abdominal pregnancy, but his only comment is that the pregnancy took place in the left tube, which partially ruptured, but as the amniotic sac remained intact the fœtus was able to develop for four months.

Kynoch (*Trans. Edinburgh Obst. Soc.*, 1925, XLV, 159) describes a case of abdominal pregnancy secondary to tubal gestation at term. He states, 'it may I think be assumed that the primary implantation of the ovum was in the right Fallopian tube and by gradual erosion or giving way of the upper wall had passed with unruptured membranes into the abdominal cavity'. Curiously enough in Kynoch's case the placenta was peeled off with but little hæmorrhage while the sac was so firmly adherent to peritoneum that it was plugged with a Mickulicz tampon and its edge sutured to that of the abdominal wound. Kynoch quotes Werth of Kiel and Taylor of Birmingham, as stating

that such cases might follow erosion or gradual stretching of the upper wall of the tube with the escape of the fœtus into the abdominal cavity surrounded by intact amnion.

The question of course which remains to be settled is whether it is (a) an erosion with the escape of the fœtus out of the tube, (b) a gradual stretching of the tube, the fœtus being retained within the stretched wall of the tube, or (c) an erosion of the inner wall of the tube the fœtus escaping into the lumen of the tube, which otherwise remains intact, simply stretching to accommodate the growing fœtus. Schumann's remarks on placentation are of interest as bearing on the case described by us. According to him tubal and uterine placenta are identical in formation, with this difference, that as development proceeds the thin tube wall, lacking a true decidua serotina, is easily invaded by the trophoblast and syncytial cells, since no active connective tissue reaction is set up in the tube by the presence of foetal cells. The villi rapidly penetrate the tubal wall and are soon found beneath the serous coat, which is invaded and hence ruptures. The tubal placenta also lacks nutrition, the false sinuses not being comparable to the rich blood supply of the uterine wall, a probable explanation of the great number of pathological embryos found in extra-uterine gestations.

Why most rupture and a few go on to term is explained by Schumann as due to an inherent phylogenetic action in certain tubes enabling them to resist the erosive action of the villi and to accommodate themselves to the immense distension of the growing fœtus, or perhaps to some primitive reversion of the tube to its uterine origin permitting it to take on, to some extent, the morphology of the uterine cornu of the lower animals.

In advanced cases the structure of the foetal sac is comparable to that of an intra-uterine pregnancy. It is greatly thinned out, the muscular fibres rapidly undergo a metaplasia into connective tissue, though they may always be found unchanged in greater or lesser number. In some cases muscular elements may be very pronounced and so dense that contractions are so marked as to suggest a uterine body.

Spackman (*Indian Med. Gaz.*, LXVIII, 511) describes a case of full-term gestation, where the ampullary portion of the right tube was dilated to form a gestation sac from which the child was delivered. The placenta was widely adherent to the under surface of the sigmoid flexure and to the back of the uterus and peritoneum of the lower abdomen, and could not be entirely removed on account of the danger of interfering with the blood supply to the sigmoid colon. Here is a case where the amnion has remained intact, allowing the fœtus to develop to full term, but the tube has ruptured,

and the placenta, growing through the rent, has made attachments to surrounding structures.

In the case recorded, it is our opinion that the Fallopian tube remained intact, and this opinion we base on the fact that neither amniotic sac nor placenta were adherent to any surrounding structure, but were contained in a primary gestation sac, covered by tubal peritoneum, which could not normally, and did not, form any adhesions to surrounding structures.

A NEW OPERATION FOR THE CURE OF ASCITES

By F. C. FRASER

LIEUTENANT-COLONEL, I.M.S.

Superintendent, Headquarter Hospital, Coimbatore, South India

THIS operation rests on the evidence of but a single case, but so many cases of ascites are intractable to all known methods of treatment, both medical and surgical, that it seems worth while drawing attention to this new operation. Moreover, it was performed in a most intractable case, in which all other treatments had failed, and it was attended with such instantaneous relief that further proofs of its efficacy need not be awaited.

The patient, aged 3½ years, was admitted to the Headquarter Hospital, Coimbatore, on 13th March, with a history of ascites which had developed after an attack of jaundice four months before. The ascites was of a very high degree, the patient resembling an enormous barrel from which the puny limbs projected like sticks. He was quite unable to walk or even stand. Portal cirrhosis was diagnosed and the usual medical treatment, as well as paracentesis abdominis, adopted. As he failed to improve under treatment, the parents took the child away to Madras on the 24th March and he was admitted to the General Hospital where he remained for some three months, paracentesis being performed no less than seventeen times. As he was steadily declining and the ascites was not bettered, the parents returned to Coimbatore and had the child readmitted to the hospital here on the 3rd July. His condition then was decidedly worse, the ascites more accentuated and the epigastric angle completely obliterated by the distension of the abdomen.

First operation.—At the request of the parents I performed abdominal section on the 11th July. The omentum was split into two halves from its free border to its root, and each half was carried between the muscles of the anterior abdominal wall and anchored there by sutures.

The wound healed by first intention, but paracentesis had to be performed again as early as the 22nd July to save the young scar from bursting open from distension. This first operation was thus a complete failure as so often happens. Throughout August paracentesis had to be performed repeatedly.

Thinking over this case one morning, I wondered if the procedure adopted in the radical cure for hydrocele would have the same beneficial results in a case of ascites. True, it would

INFANTILISM AND CIRRHOSIS OF THE LIVER

By M. V. RADHAKRISHNA RAO, M.B., B.S.

Research Fellow, Andhra University

(From the Department of Pathology, Medical College, and King George Hospital, Vizagapatam)

GROWTH may be delayed or arrested in several conditions. Though the endocrine glands are mainly concerned in regulating growth, other tissues in the body are also responsible to some extent. Generally speaking, delay or arrest of growth can be classified under two headings,

(Continued from previous column)

not be possible to turn the peritoneal sac inside out, but one could cut away as much of the parietal peritoneum as possible, which would amount to the same thing. With the consent of the parents, this was done on the 1st September.

Second operation.—An incision running from just above the pubes to well above the umbilicus was made and the peritoneum on each side of the wound stripped up by gauze dissection nearly to its reflection on to the ascending and descending colons, the general oozing of blood being easily arrested by hot saline gauze swabs. The abdomen was then closed with a continuous silk suture, no drain being put in. A small dose of morphia was given prior to the operation to abolish any chance of shock.

The wound healed by first intention, the stitches being removed on the eighth day, by which time but very slight refilling was going on. The size of the abdomen became static on the 12th day after the operation, and from then onwards began rapidly to decrease in size. Simultaneously, a very striking network of veins sprang into appearance on the thorax, some of the veins being quite varicose and extending to above the clavicles. Improvement was steady from then onwards until the 20th September on which date the child was discharged cured. I last saw him on the 21st October, when he had assumed the normal size of a child and was running about happily.

The features of this case were the intractable nature of the disease, the child having been tapped no less than twenty-five times, the failure of all other methods followed by instantaneous relief after the above operation, and, lastly, the dramatic appearance of the portal-systemic anastomosis so shortly after the operation.

It will be argued against the operation that the danger of intestinal obstruction from adhesions is too great a risk; I am prepared to admit that there is such a risk, but frequently in these cases of tuberculous peritonitis where the gut is hopelessly matted together and to the abdominal wall the patients exist comfortably for many years. The outlook in intractable ascites is so hopeless that almost any risk is justifiable.

dwarfism and infantilism. 'In dwarfism, growth alone is affected, whereas infantilism consists in an arrest or retardation, not of growth only, but of the whole development including the secondary sex characters' (Hutchison, 1931).

Infantilism associated with congenital syphilis and cirrhosis of the liver has been described by Hutchison (1931) and Gilford (French, 1928). Fittipaldi (1931) described cases of infantilism associated with disorders of the hepato-splenic apparatus and concluded that both infantilism and the hepato-splenic lesions were expressions of an abnormal constitution.

Cases of familial hepatic infantilism were reported by Exchaquet (1931). He showed that retardation of development in these cases was undoubtedly due to the condition of the liver. He considered that the infantilism was due to lack of carbohydrates, as he found hypoglycæmia in these patients. Poynton and Wyllie (1926) pointed out that familial tendency and infantilism are the special features of cirrhosis of the liver in children.

The following case is an example of infantilism associated with syphilitic cirrhosis of the liver.

Case notes. History.—T. N., a Hindu male, about 15 years of age, was admitted into the medical wards of the King George Hospital, Vizagapatam, on 6th November, 1931, for swelling of the abdomen of four months' duration. About one year prior to admission into hospital, he was examined in his school by a medical inspector, who reported to the parents that the boy had an enlarged liver. He was under allopathic treatment from that time. The liver, though diminished in size, became hard and the abdomen gradually began to distend with fluid.

The patient was the sixth surviving child in the family. Two children died at about the ages of two years and eight months, respectively. There was no history of similar trouble in any of the other members of the family.

The patient was not addicted to either alcohol, in any form, or tobacco. There was no history of malaria nor other fever, nor of dysentery. The main articles of the diet were rice and *cholan*; *dhal*, condiments, milk and milk products were used only occasionally, but chillies were taken daily in excess; meat and fish were taken about once a fortnight.

Physical examination.—The patient was extremely emaciated, with practically no subcutaneous fat and all the bony points were very prominent (see figure 1). He was slightly anæmic with a sub-icteric tint of the conjunctivæ. There was slight bossing of the parietal eminences. The lymphatic glands in both the posterior triangles of the neck were enlarged, palpable and shotty. The bridge of the nose was slightly depressed. There was no scarring around the mouth, and no signs of interstitial keratitis were seen. All the teeth were well erupted, with the exception of the last molars (which were absent) in the upper jaw and on the left side of the lower jaw. The patient's height was 45.5 inches, and weight 38 lbs. The maximum diameter of the head was 19.5 inches. The temperature, and the pulse and respiration rates were normal.

The muscles of the chest were markedly wasted. Both the lungs showed diminished resonance over the bases, with numerous coarse râles. The heart was normal. The pulse was regular but of poor volume and tension. The maximum circumference of the chest was 23.0 inches.

The abdomen was markedly distended with free fluid and the flanks were bulging. The skin of the abdominal wall was tightly stretched and shiny. The superficial veins of the abdominal wall were much distended and the flow of blood in them was from below upwards. There was a hernial protrusion of the right inguinal sac, the contents of which could be reduced into the abdominal cavity. The left lobe of the liver, which could be felt 1½ inches below the xiphisternum, was hard, with a finely granular surface and a sharp edge. The maximum circumference of the abdomen was 28.0 inches.

The extremities were very thin and the skin over them was dry and inelastic. There was no œdema of any part of the body. No enlargement of the epiphyseal ends was noticed. The epitrochlear glands were definitely palpable and shotty. The knee jerk was not elicited on either side.

The general development of the patient was very poor and the secondary sexual characters were entirely absent. The head was proportional to the rest of the body. The patient appeared like a boy of nine years.

Fig. 1.

The axillary and pubic hairs were absent and the genitals were infantile.

Laboratory findings: (a) Blood.—

Hæmoglobin	..	80 per cent.
Red cells	..	5.25 millions per c.mm.
White cells	..	13,125 per c.mm.

Differential count.

Polymorphonuclear neutrophils	77 per cent.
Lymphocytes	.. 17 " "
Eosinophils	.. 3 " "
Monocytes	.. 2 " "
Mast cells	.. 1 " "

The blood smear showed marked anisocytosis and slight poikilocytosis of the red cells; no nucleated red blood cells or pigmented mononuclears were seen. The

coagulation time was 4 minutes and 33 seconds. Haemolysis of the red cells (fragility) began in 0.4 per cent saline and was complete in 0.25 per cent saline. The van den Bergh's reaction was—direct, delayed (faintly positive). Halometer reading of the blood film was 4.7 ($= 7.32 \mu$, i.e., normal).

The agglutination test with dysentery organisms was negative. The Wassermann reaction was strongly positive; the test was repeated with the same result.

(b) *Urine*.—This was dirty yellow in colour, slightly turbid and acid in reaction. Sugar, albumin, acetone, bile salts and bile pigments were absent. Phosphates, urates, indican, urobilinogen and urobilin were present. Microscopically, numerous triple-phosphate crystals and urates were found; no cells or casts were seen. The urica-concentration test showed that the kidney function was good.

(c) *Faeces*.—The motions were solid and brownish-yellow in colour; and many whip-worm and round-worm ova were present.

(d) *Ascitic fluid*.—This was bile-stained, clear, faintly alkaline in reaction, with a specific gravity of 1.007. The protein content of the fluid was 0.75 grammes per

cent. The cells were mostly lymphocytes, and the cell count was 40 per cubic millimetre.

The Wassermann reaction of the ascitic fluid was strongly positive. The agglutination test was positive for *B. dysenteriae* (Flexner) in dilutions up to 1 in 32. The fluid was sterile on culture.

(e) *Von Pirquet's test*.—Negative.

(f) *Röntgenograms*.—X-ray examination of the wrists showed that the ossific centres of the pisiform bones have appeared.

Progress and treatment.—The patient was afebrile during his stay in the hospital. He was given a course of sulpho-stab (14 injections) beginning with 0.3 gramme and gradually increasing to 0.45 gramme, together with injections of mercury. Iodides and mercury were administered orally. To improve the general condition iron and arsenic injections were given on alternate days and cod-liver oil was administered orally. Paracentesis of the abdomen was performed seven times while in the hospital, to relieve the pressure effects of the fluid. When the patient was discharged from the hospital on 23rd April, 1932 (after a stay of nearly 4½ months), his general condition was much improved and the fluid in the abdomen was not accumulating as rapidly as before. But the size of the liver and spleen did not show any diminution. The patient reported himself on 11th July, when he was readmitted into the hospital. Paracentesis of the abdomen was not done during this interval, as there was only a small quantity of fluid in the abdomen. His general condition showed marked improvement (figure 2).

Comment

The physical examination, the strongly positive Wassermann reactions of the blood and ascitic fluid, and the marked improvement of the patient after the administration of arsenic and mercury, clearly show that the case is one of syphilitic cirrhosis of the liver. The fact that the patient responded to treatment shows that the cirrhosis of the liver was not very advanced, although it had already manifested itself in portal obstruction.

As the ossific centres for the pisiform bones have appeared, it can be taken that this patient's age was above 12 years (Waddell, 1921). According to Powell (1902) the appearance of the 'wisdom' teeth varies from 14 to 27 years. As his right lower wisdom tooth has already appeared, the minimum age of the patient may be fixed at about 14 years.

French (1928) remarks that 'in determining whether development is implicated, stature, ossification, and sex development are of great but not decisive importance. Thus infantilism may coexist with gigantism; and the ossification in some patients with symptomatic infantilism is not only not delayed but is definitely premature'. In this case, though the ossification appears to be normal, the development is retarded. The sex development is very poor.

The absence of any endocrine disturbance, together with the improvement in the general condition of the patient after the treatment, point to the infantilism being probably due to the syphilitic cirrhosis of the liver. In this case, the degree of infantilism was not marked and the general condition bettered with improvement in the condition of the liver. As Hutchison (1931)

A NEW INTRAVENOUS ANÆSTHETIC: EVIPAN SODIUM

By G. H. FITZGERALD, M.R.C.S., L.R.C.P. (Lond.)
D.T.M. & H. (Lond.), D.P.M. (Cantab.)
MAJOR, I.M.S.

Civil Surgeon, Meerut, U. P.

THE general lack of gas-and-oxygen apparatus in this country renders the task of the surgeon not infrequently one of unnecessary difficulty, and there must be few who have not at some time or another wished for a means of inducing anæsthesia for short periods, rapidly and without risk or previous preparation.

Through the courtesy of the Indian representatives of the German firm of Bayer-Meister Lucius, I have recently been able to make a fairly extended trial of a new substance, evipan sodium, which is introduced intravenously, and which will produce anæsthesia lasting—according to the quantity administered—up to 45 minutes.

This drug, which is a derivative of barbituric acid of complex formula, is a white powder, readily soluble, and is put up for use in ampoules together with 10 c.cm. of distilled water, so that all that is required is to prepare a solution in a 10 c.cm. syringe.

The technique of injection is extremely simple, the requisite dose is injected into an arm vein, the first few cubic centimetres being injected *extremely slowly*. (I personally make a rule of two minutes for the first two cubic centimetres and thereafter two cubic centimetres per minute; this is perhaps erring on the side of

(Continued from previous page)

remarks 'the degree of infantilism in this group (symptomatic infantilism due to severe constitutional disease) is usually but slight, and the clinical picture is dominated by the primary disease, on which also the prognosis depends'.

I wish to express my thanks to Dr. G. Dinker Rao, first physician, and to Dr. P. Kutumbaiah, second physician, King George Hospital, Vizagapatam, for permission to publish these case notes, and to Dr. P. Kesavaswamy, radiologist of the hospital, for the photographs.

extreme caution.) Leakage into the tissues is harmless.

The amount to be given varies according to age, body-weight, length of anæsthesia required, and the general condition of the patient. The makers suggest, as a working rule, that if short anæsthesia is required, double the dose required to make the patient fall asleep (shown by his ceasing to count), and for a long anæsthesia, three times this amount; i.e., if the patient falls asleep after 3 c.cm. have been given, 6 c.cm. will suffice for such operations as opening an abscess or extracting a tooth, whilst for more prolonged work 9 c.cm. will be required. A safe maximum dose in a healthy adult is about 10 c.cm. and this amount I have never exceeded, nor should it ever be necessary to do so.

By the patient, all that is noted is an intense and uncontrollable drowsiness, and it is remarkable that even the most highly-strung subjects show no signs of excitement or apprehension as the drug is being given. Preliminary narcosis can thus be given whilst the patient is in bed, and the psychic trauma of removal to the theatre entirely obviated.

As sleep is induced, the respirations deepen, and there are often muscular spasms of the head, arms and legs. There is slight irritation of the bronchial mucosa, and patients with any tendency to cough, frequently do so for a time until narcosis has been fully established; indeed if a small dose only has been given the cough and muscular twitching may continue throughout. A full dose, however, abolishes this. In actual administration, relaxation of the jaw muscles is the sign to look for, the mouth falls open, the patient is now completely anæsthetized and the operation can be commenced, though as noted above, if longer anæsthesia will be needed, 50 per cent to 70 per cent more than this must be given.

I have now used it in a very large variety of surgical procedures, from opening abscesses and removing cysts to prolonged abdominal operations. In but one instance did any untoward result follow, namely in a debilitated man with a large abscess of the calf. Here 6 c.cm. only were given, but I abandoned my rule of two minutes for the first 2 c.cm., and gave them in one minute, the whole injection occupying about 2½ minutes. The patient became pulseless, respiration stopped, and nearly half an hour of the most vigorous restorative treatment were required before respiration was again established, though it is notable that on recovery the patient felt none the worse.

This was at the outset of my trial of the drug, and so impressed itself upon me that I insist on the injection being given as stated, though the makers claim that 4 c.cm. per minute may be given.

A trial was made of it in cataract extraction, but here it did not prove an unqualified success. As prolonged anæsthesia was not considered

necessary, 5 c.cm. only was given; at this stage there was much coughing, and the patients moved their heads from side to side; possibly a bigger dose would have been more successful, but it was feared that as consciousness returned there might be restlessness with interference to bandages. The pupil also became dilated and one missed the co-operation of the patient.

Apart from minor work, where it has proved invaluable, we have been employing it increasingly in operations where prolonged anaesthesia is required. Here the effect of the evipan is reinforced from the start by light chloroform anaesthesia. The patient, already deeply unconscious, is given a few whiffs of chloroform by a Junker's inhaler from time to time. There is no stage of excitement, and post-anaesthetic vomiting or toxæmia is unknown.

In two recent cases, one the removal of a massive renal tumour, and the other of a broad-ligament and ovarian tumour, both lasting over two and a half hours, six and seven draehms respectively of chloroform were used, and the patients at the end of the ordeal were in remarkably good condition, nor did they give any cause for anxiety whilst the operation was in progress. Relaxation is quite good, though of course not so perfect as under a spinal analgesic, but respirations are slow and regular, a great advantage in abdominal work. To those with experience of anaesthetics as generally administered in this country, these are points which need hardly be stressed!

In a series of blood pressure estimations made before and after operation under evipan, it was found that blood pressure fell between 10 to 15 mm. Hg.; this seems unimportant and may equally have been due to shock, though a similar fall was noted in experimental rabbits.

After-effects appear to be absent. The patients wake up as if after a natural sleep and there are no toxic symptoms.

To sum up, in evipan sodium we appear to have a most useful addition to the seemingly inexhaustible barbituric acid series, which can be used effectively as a substitute for gas and oxygen and as a 'chloroform sparer'. It can be given by the operator himself, if single-handed, and it requires nothing more than a Record syringe for its administration. With reasonable care it is perfectly safe and leaves no unpleasant after-effects.

MENTAL SUGGESTION IN EVERYDAY LIFE

By W. NUNAN, M.D.

Police Surgeon, Northcote Police Hospital, Bombay

LET us take up the morning paper—irrespective of its political colour—and look at the advertisement columns. Here we have a testimonial by a well-known actress in which she

refers to the bloom of youth imparted to her skin by the use—morning and evening—of 'Dr. Cutiele's Skin Food'. Across the page a well-known African explorer and big-game hunter of international reputation spreads himself over a quarter column in large type in praise of a preparation presented for the relief of suffering humanity—at Rs. 2 per tin—by a philanthropic chemist, a preparation which the said explorer and big-game hunter guarantees to be an immediate cure for any human surgical ailment. Overleaf is a photograph of a famous cinema star, with shining regular teeth exposed to our admiring gaze in a broad expansive smile. Beneath this picture, the handsome hero of the 'movies' informs us that he uses Dento regularly—to which fact he ascribes the snowy whiteness of his dentures.

In the sporting section of the paper we read that, if we will only be careful to use none but Roeket's famous tennis balls, we shall be able to play tennis better than Suzanne Lenglen, or that if we wield only Wickets' unrivalled bat, we shall ensure our being selected to play for the Presidency against the M. C. C.

Now let us turn to a number of the *British Medical Journal*, or *Lancet*, just arrived by the English mail. On the very second page we read that the world-renowned chemists, Haggelheimer, whose immense laboratories are situated on the banks of the romantic, castellated Rhine, have recently isolated a new substance possessing a specific inhibitive effect upon the functions of the autonomic nervous system. It is said to have been proved clinically to be the *only* effective inhibitor of the vagus, and is indicated for the treatment of disturbance of intestinal motility, hyper-secretion, pyloro-spasm, spastic constipation, mucous colitis, biliary colic, bronchial asthma, or spasmodic neurosis.

On another page we read of a proprietary remedy which supplies the physiological stimulus to the endocrine glands, whose functional activity determines the normal catamenial flow. It is stated that when these internal secretions begin to fail at the period of the menopause, the preparation in question acts both by substitution and by homo-stimulation. Any female patient, then, who is approaching 'the change of life' in order to be rid of all the disturbances, physical and mental, peculiar to that critical period of her mundane existence, need only follow the simple directions on the bottle 'one or two tablets three times daily' while, as a sop to the anxious and potentially hostile practitioner, the subtle advice is added, 'as directed by the physician'. The advertisements in the medical press are as cleverly worded as any in the pages of a penny paper or monthly magazine of fiction.

Now let us turn from our papers and look out of the window to observe the passing show—across the street, below a mighty hoarding on which are displayed the advertisements of motor

cars, petrol, tyres (more mileage at less cost), baby foods, beer, whisky, Charlie Chaplin, watches, gramophones, radio-sets, pianos, cheap return tickets (1st, 2nd, and 3rd class) to Poona races (including admission to the course), binoculars (as example of association of ideas), vacuum-cleaners, safety-razors and prophylactic tooth-brushes surrounding a highly-coloured picture of an elderly well-groomed gentleman with eye-glass flying behind him, sliding down the banisters under the impulse of the 'Kruschen feeling'. One's attention is interrupted by a shout, a yell of pain, and the screaming child is caught up in the arms of a loving mother. Attention is drawn by the sobbing and indignant youngster to his bruised knees, and to his dust-smudged nose; whereupon the mother caresses the injured and painful areas, assuring him that the pain has gone. A moment afterwards the boy is once more careering on his scooter to the imminent peril of the innocent pedestrians. She leaves him only to rush to the perambulator in which the baby has started screaming. A soothing hand upon the restless little head, a monotonous, crooning lullaby, and master baby snuggles down to resume his disturbed slumbers.

In these poor pen-pictures of a few phases of the daily morning round, I have tried to put before you and to illustrate some examples of the mighty, surging, ever-present, ever-functioning power of suggestion.

There are good suggestions and bad suggestions. I know a man, perfectly healthy in all respects, who insists on his chest being carefully examined at frequent intervals and his weight noted for future reference and comparison, because some medical man a few years ago told him there was a suspicious patch in one of his lungs, with an x-ray photograph to confirm the diagnosis. I have a shrewd suspicion that he does not rely on my repeated assurances that he is as well as I am myself, but that he visits other practitioners for confirmation.

Luckily, he is rich enough to indulge in his hobby, and pays my fees regularly.

I know another man, intelligent, well educated, who for eight years worried—night and day—lest he should suddenly become totally blind, because of a careless word spoken by a London oculist, so much for malefic, or harmful, suggestions.

At home, in my native Limerick, I knew an old man, well over 80 years of age, strong, hale and hearty, who smokes tobacco strong enough to asphyxiate the average person with its fumes. During my leave in 1925, I visited him. In the course of conversation he gravely informed me that he had been suffering from an incurable disease for the last 45 years, and that none of the local medical men had succeeded in discovering either what it was or a remedy for it. If I had smiled I should have incurred his deadly enmity, so I gravely commiserated with

him on the shortcomings of modern medicine in diagnostic methods and therapeutics. This is a typical case of malefic self-suggestion, which, in this instance, fortunately, had not only not done the patient any harm, but had actually given him something of interest to talk about to any new-comer to the neighbourhood—a pastime which he thoroughly enjoyed. To cure him of this obsession would be to deprive him of a cheering pastime and sadden his declining years.

Desperate diseases or conditions sometimes call for desperate remedies, and I remember a very acute attack of diarrhea with violent pain, straining, blood and mucus—the classical dysenteric signs and symptoms—from which I suffered in 1916, when travelling in a horse waggon on the Bagdad Railway from Bagdad towards Samarra. The attack lasted for about 24 hours, and left me prostrate. On arrival at a halting place in the desert, I staggered across the sand into a medical officer's tent, and asked for something to eat, as by this time I was completely empty. All he had was a large lump of stale plum cake and a tin of sausages. I finished both with great gusto, and I never had another loose motion, or a pain or ache of any kind. The medical officer, aghast at my rashness, declared that my action was suicidal and predicted disaster, but his malefic suggestion was apparently rejected by my subconscious mind, for here I am—though I do not recommend the remedy.

This brings us to the word itself—suggestion. What do we mean when we speak of 'suggestion'? Many will answer—'hypnotism'. This reply entails another question—What is hypnotism? Let us analyse the word: *Hypnos*, as we all know, is a Greek word meaning sleep. Hypnotism then must mean a method of putting people to sleep, or at least must have something to do with sleep. Hypnotism is a word invented by an English physician, Braid. Later in life he regretted that he had invented the word, for in the great majority of cases it is a misnomer, since there is no sleep. Let us turn again to the answer, 'suggestion is hypnotism'. Well then, we must again ask, how is a state of hypnotism produced? The true answer is 'by suggestion'.

We must then arrive at the illogical conclusion that suggestion is caused by itself which is, as Euclid says, absurd. The truth probably is that all hypnotism is suggestion, but all suggestion is not hypnotism. The power of suggestion or rather of self-suggestion—and remember that all suggestion to be successful must intimately be transformed into self-suggestion—can be aptly illustrated by the simple experiments given by the late Monsieur Coué of Nancy—a name which will be remembered as that of one who showed the man in the street, after thousands of years, the mighty power of the human mind over the human body, for good or

for ill. 'Imagine', says Coué, 'that you are sucking a juicy very sour, lemon and your mouth will instantaneously and inevitably begin to water; you will, in technical language, salivate profusely. The very fact of imagining such a thing, of suggesting such a thing to yourself, has produced the reflex functioning of the salivary glands—just as if you had really sucked a sour juicy lemon. Again, you have only to imagine a slate pencil being scratched across a slate to produce grimaces, contortions, and bodily shiverings. Just as it is thus possible to produce disagreeable sensations by merely thinking of, or suggesting to ourselves, unpleasant things, it is also possible to produce agreeable sensations by thinking of pleasant things.

Our subconscious minds record all ideas which are presented to them, and it is for us to see that the ideas recorded are those of health and happiness, rather than of disease and misery, seeing that the subconscious mind, sooner or later, transforms into facts and verities the ideas which it records, when the ideas are not opposed to strong moral conviction and are not inimical to our interests. Between ourselves and our subconscious minds, however, or between the operator and the subconscious mind of his patient, there is a powerful barrier—the barrier of the conscious mind.

Let us take a concrete example—a man comes to a doctor's office and says 'Doctor, I have had terrible neuralgic headaches over the left side of my forehead for some months past—I have tried all sorts of remedies, but the headache recurs at regular intervals—usually about 5 p.m.'

The doctor pricks up his ears on hearing the last few words—for here we have the factor of expectation showing its ugly head.

As the hands of the office clock crawl slowly round towards 5 p.m.—whether standard or Bombay time—the tortured nerves begin to vibrate and across the supra-orbital area is felt a blinding sickening hopeless agony. The doctor makes as thorough an examination as possible of the physical condition, after going into the recent and remote medical history, diet, habits, mode of life, etc., in accordance with the exhaustive methods he has learnt so laboriously during his medical course, and satisfied that the patient is otherwise well in body and in mind, except for the natural depression of spirits due to his recurring pain, the doctor proceeds to put into practice the theories of suggestive therapeutics.

If he tells such a man 'you have no pain, because there is no physical basis for it nor organic disease to give rise to it. The pain is imaginary. You must not think about it', the reply will probably be unrepeatable and unprintable. At any rate the patient will seize

his hat and rush out of the office to visit a real doctor or a doctor who is not suffering from temporary insanity. Why? Because he *knows* he has a pain, his conscious mind informs him of the fact, and keeps drilling that suggestion of pain—recurring pain—into his subconscious mind, which accepts the suggestion without argument, analysis or criticism, and proceeds daily to transform the suggestions into verities and facts. As a matter of fact, his visit to the doctor will have increased the pain and implanted the idea of pain more fixedly in his mind. A suggestion is the implantation or the development of an idea, or ideas, in the mind of the patient. The idea may be implanted by the subject himself, self-suggestion (or as it is called sometimes auto-suggestion), or by the operator (hetero-suggestion or simply, suggestion). In order that suggestions may be accepted, a patient, ordinarily, must be rendered more suggestible.

It is the greatest mistake in the world to think that the highly-strung, self-centred, neurotic person is very suggestible. On the contrary, such a patient is likely not to respond to suggestion-therapy.

Sidi thus enumerates the conditions which tend to induce susceptibility to suggestion:

- (1) Fixation of attention.
- (2) Monotony.
- (3) Limitation of muscular movements.
- (4) Limitation of consciousness.
- (5) Inhibition, or the prevention of the intrusion of foreign ideas.

These conditions are all very well, and no one denies the necessity for their fulfilment before suggestion can succeed in a particular case. But how many of us here present can fix our attention? I know two medical students in Dublin who for two solid years played cards during lectures. How many of us can limit our consciousness, though we may apparently be able to limit our muscular movements? I say apparently because it is very rarely that the average modern man—and even more rarely that the average modern woman, who is, as we are all aware, getting more and more restless—can relax.

How many of us can relax our muscles? Let me make a simple test. Raise your arm until it is at right angles to your body and rest the hand upon mine. Do not press up and do not press down. Relax the muscles of the shoulder, upper arm, forearm and hand and let the weight of the whole arm rest upon my hand as if it were the arm of a corpse in which rigor mortis had not developed or had passed off. I now suddenly withdraw my supporting hand. What happens? Nine times out of ten, the arm either remains horizontal in the air, or drops a little way and then remains fixed for a moment, to drop again when the subject

remembers to let it fall. The muscles have not relaxed. Relaxation then is not so easy as it sounds.

Again, raise both arms above your head, and let them drop simply forward. If you have relaxed the muscles, each arm should drop by its own weight and swing like a pendulum beside the body. I have perhaps gone far enough to show you that the advice to relax is easily given but not so easily carried out.

Which of us again can produce in ourselves limitation of consciousness? A man, who for one reason or another suffers from insomnia, goes to bed determined to sleep. The very determination defeats its object, sets in action what has been well called 'the law of reversed effort', and he tosses about restlessly and sleeplessly throughout the night. When this has gone on for some successive nights, he goes to bed with the expectation of not sleeping, and his expectation is realized. He does not sleep—and so a vicious circle is set up. His sleeplessness in the first instance may have been due to financial or other troubles. Through the weary night he worries over them, and in the morning, weary and depressed, he finds himself less able to face his work and troubles, which therefore loom ever larger and more insurmountable, the whole sequence of events leading to a state of hopelessness, depression and despair. This is not a rare or fanciful picture. The medical man in general practice meets such cases daily. Woe betide the unfortunate who resorts to drugs—no matter what their nature—with or without 'the directions of the physician', and here let me for a moment ride a hobby of mine—at any rate it is a firm conviction—regarding the abuse of bromides. *Bromism*—the foul tongue—the stinking breath—the acne—pustular—red—disgusting—the moroseness—the dull-wittedness—the depression—the progressive cerebral degeneration—how many mental cases do we see go steadily down hill to hopeless and complete dementia, because, forsooth, 'bromides keep the patient quiet'.

The mental hospital of the future will, in my humble opinion, have two sections. In the first will be placed the incipient cases of mental derangement, which will be treated by psychotherapy by physicians who have specialized in the subject; many of these patients will never find their way into the second section, where will be accommodated only those unfortunates who, on account of serious organic central nervous deterioration or destruction, must be pronounced incurable. My time draws to a close, and I will ask you to have patience while I give you a résumé of three or four out of many typical cases that I treated by suggestion with satisfactory results:

(1) Male, aged 45, a case of depression and insomnia which had lasted several months following the death of a son.

Result.—Patient slept 6 hours after the first treatment, 7 hours after the second and 8 hours after the third and was, in his own words, 'a different man'.

(2) Female, aged 22, a case of pseudo-paralysis which had lasted 2½ years, contracted flexors of upper and lower extremities resulting in almost complete crippling—not only unrelieved but aggravated by tonics, massage, high-frequency currents, injections, etc., or rather, aggravated by the successive failures of these procedures to ameliorate the distressing condition.

Result.—Patient moved right wrist at second sitting, moved both wrists—full extension and flexion 20 times—at the third sitting, and now uses wrists and ankles freely.

(3) Male, aged 32, a case of obsession (*psychasthenia*); the patient was worried by imaginary armed Pathans; he had applied to the police for protection and ultimately refused to leave his house, lest he should be assaulted on his way to office. He had written his resignation to his employer and was in great mental distress.

Result.—At the second treatment, the patient tore up his resignation and within a week had resumed complete charge of his department.

(4) Male, aged 38, adipose, suffering from cardialgia, pain in heart had lasted about two years—no organic disease. Pain removed at first treatment; further treatment refused as being unnecessary—pain being absent. After some days, patient returned terrified. He had mounted his motor-cycle, when pain returned, more severe than ever.

Further treatment advised; these treatments given.

Result.—The patient confident that pain will not return. Twelve months have elapsed—I saw the patient a few days ago in the High Court, well, happy and entirely free from pain.

Conclusion

Now it only remains for me to quote to you the words of Bacon in his *Essay on Studies*:—

'Read not to contradict, nor to believe; but to weigh and consider'.

I will be asked 'Is suggestion then a cure-all—a panacea?' By no means—suggestion will often fail where medicines will succeed, just as it will often succeed where ordinary therapy has failed. I claim merely that suggestion is a powerful additional remedy, hitherto neglected. Suggestion will always fail where patients are hostile or non-receptive.

In conclusion, it is my belief—founded upon my own personal experience in active practice—that in most cases in which we can rely upon the intelligent co-operation of the patient—on essential consideration—we can nowadays, remembering that every physical ailment has a mental coefficient, give a hopeful and re-assuring answer to such a terribly piteous appeal as that of Macbeth to the doctor in the last act of Shakespeare's great tragedy:—

Can'st thou not minister to a mind diseased,
Pluck from the memory a rooted sorrow,
Raze out the written troubles of the brain,
And with some sweet oblivious antidote
Cleanse the stuff't bosom of that perilous stuff
Which weighs upon the heart?

NOTES ON THE TREATMENT OF ORIENTAL SORE WITH BERBERINE ACID SULPHATE*

By RABINDRANATH CHATTERJEE, M.B.
S. V. S. Marwari Hospital, Calcutta

ALTHOUGH this particular disease is rare in Calcutta, and only occurs amongst visitors from other provinces, we have had occasion to treat as many as two dozen cases at the Marwari Hospital during the course of the last two years and a half; it is needless to say here that all our patients were Marwaris, residents of Central India.

The only treatment that our patients received was a local infiltration of the sores with a 2 per cent solution of berberine acid sulphate, the brand we used being May & Baker's 'Orisol'.

Our procedure in treating these cases was as follows:—In cases in which there were more than two sores, at each sitting we infiltrated two only, each sore receiving not more than two punctures. One pair of sores was treated every second day. When each pair had received their initial infiltration, we again started with the first pair. The total maximum dose used at every sitting was 2 c.cm. of 2 per cent berberine acid sulphate. Not a single patient in our series ever showed any sign of local reaction or any toxic symptoms. From our series we have observed that to cure a patient, say with two sores, he will have to undergo in all 12 infiltration sittings with a total of 48 punctures, that is 24 punctures for each sore, and a total dose of 24 c.cm. of 2 per cent Orisol, during a total period of 24 days.

Pain.—It will be admitted that any injection will cause some degree of pain; in these infiltrations we have observed nothing more than the amount of pain that would normally be expected following an injection of this amount of fluid. Another question that has been raised previously is the possibility of the prior application of one of the new anaesthetics, e.g., percain, to the ulcer for a few minutes before infiltrations. We have never used any of these anaesthetics and have never met with any instance on which we considered that they were necessary.

For the performance of infiltration, all that is required is an air-tight glass syringe with a fine sharp needle.

In conjunction with the infiltration method, we have used of late a dressing of 2 per cent berberine acid sulphate ointment; these dressings have been found to keep the sores in a very clean and healthy state. Whether this ointment will lessen the number of infiltrations required we have not yet determined.

Conclusion.—Orisol, as used by us, has given entire satisfaction, without a single failure and

AN UNUSUAL FORM OF TUBERCULOSIS (REPORT OF A CASE)

By A. N. GOYLE, M.B., B.S., Ph.D. (Lond.)

A. VASUDEVAN, M.B., B.S.

and

K. G. KRISHNASWAMY, M.B., B.S.

(From the Department of Pathology, Medical College, Madras)

LARGE tumour-like conglomerate tubercles of the liver are so rare that no apology is needed for the publication of a detailed report of the following case:

History and course of illness.—Venkanna, a Hindu male, aged 36 years, was admitted to the Government Mental Hospital, Madras, on 5th July, 1929, with mental symptoms. In June 1931 he had pain in the joints more marked in the right knee, which disappeared under treatment. From February 1932 he had dysenteric attacks which were relieved by emetine, but he continued until his death in September to have an irregular rise of temperature ranging from 99° to 102°F.

Physical examination showed an ill-nourished man with a barrel-shaped chest. Over the left base, the percussion note was hyper-resonant with diminished resistance. Breath sounds were audible without adventitious sounds. Expectoration was moderate in amount and mucoid in character. The spleen was slightly enlarged. Blood culture gave a negative result. The Wassermann reaction of his blood was negative. Leucocytes numbered 8,000 with a relative increase of polymorphonuclears.

The stools did not contain *Entamoeba histolytica* at any time during his stay in the hospital.

Röntgen examination of the chest was interpreted as showing 'hilar tuberculosis and nothing abnormal elsewhere'.

A tuberculosis specialist examined him in August 1932, and remarked: 'No active signs of tuberculosis'.

Post-mortem examination.—This was done at the Mental Hospital, and the following report sent to us:

'A big hard mass of glands at the root of the lungs. The liver is studded with nodules of various sizes which offer some resistance to the cutting knife. The spleen shows similar nodules. There is also a small mass of glands in the left iliac region showing similar changes. The brain and other organs are normal'.

No diagnosis was made. The left lung, the kidneys, the liver, the spleen, and the glands were sent to us for examination and report. Looking at the organs, we thought the nodules represented secondary cancerous deposits.

The liver weighed 1,292 grammes. It was slightly smaller than normal. The capsule was slightly thickened. The organs did not show any marked distortion though the surface was finely granular. The surface showed numerous round nodules of varying size (plate I, fig. 1).

(Continued from previous column)

we see no reason why the drug should not be considered a specific for oriental sore?

My best thanks are due to our Superintendent, Rai Bahadur Dr. S. C. De, M.A., M.B., for his kind permission to publish this note.

PLATE I.

Fig. 1.
The outer surface of the liver showing
tuberculous nodules of varying size.

Fig. 2.
The cut surface of the liver. Note the nodules of
varying size in the substance of the organ.

Fig. 3.

Fig. 4.

There were numerous fissures on the surface of the largest nodule but no definite umbilication, as seen in secondary cancerous deposits in the liver. Some of the nodules were so small as to be just visible to the naked eye; others varied from the size of a pin-head to that of a walnut. Numerous small nodules were found to be grouped about a larger one which appeared to have formed by the coalescence of the smaller ones. The nodules were firm in consistency and were projecting from the surface (particularly the larger ones) and sharply outlined against the adjacent liver tissue. Some of the smaller ones appeared reddish-brown on account of a thin covering of liver tissue.

On section, the liver was found to be permeated with nodules similar to those seen on the surface. The largest nodule ($1\frac{1}{2}$ inches by 1 inch) situated at the anterior border of the left lobe was surrounded by a distinct fibrous capsule (plate I, fig. 2).

The liver tissue between the nodules is somewhat firm in consistency suggesting an early fibrosis.

The spleen weighed 258 grammes and was twice the normal size. The capsule was uniformly thickened. The surface, of a dark-grey colour, presented numerous discrete firm nodular masses varying in size from a pin-head to a large pea. The largest nodule was situated at the root of the organ (plate I, fig. 3). The spleen was firm, and offered some resistance on cutting. The cut surface showed a deep reddish-brown colour and was studded with nodules similar to those seen on the surface. There were a few enlarged glands at the root of the organ and these were of a greyish-white colour (plate I, fig. 4).

The left lung was deeply pigmented and on the pleural surface the outlines of the anatomical lobules were shown up with beautiful distinctness. The posterior and anterior borders of the upper lobe and the anterior border of the basal lobe showed distinct emphysema with bulbous projections. The entire organ was crepitant. Careful examination of the lung did not reveal any nodule similar to that seen in liver and spleen.

Lymph glands.—At the hilum of the lung there were two distinct masses of enlarged glands. The larger of the two was the size of a walnut, the smaller one the size of an almond. Both were surrounded by a distinct fibrous capsule. The cut surface of the glands presented a mottled appearance, dark pigmented areas alternating with greyish-white areas. The substance of the entire gland was converted into a cheesy mass which however showed no tendency to softening.

Kidneys.—Nothing of note was found.

Histological observations

Liver.—Scattered throughout the section were numerous rounded necrotic areas of varying

size, fairly sharply marked off from the surrounding tissue. The larger ones, as a rule, could be roughly divided into three zones. The central zone composed of necrotic material, under the high power, appeared partly granular and partly homogeneous with evidence of nuclear degeneration such as karyolysis and pyknosis. This necrotic centre was surrounded by a zone of round cells. The outermost zone was made up of a rather dense fibrous tissue. In nodules of smaller size, the fibrous layer was replaced by a zone of hyperaemia, and the centre consisted of a small amount of necrotic material. In the intermediate zone were groups of endothelioid cells between which round cells were seen. The endothelioid cells however were lacking in the follicular arrangement characteristic of a tuberculous follicle. Occasionally, a giant cell surrounded by endothelioid cells was seen.

The liver lobules between the necrotic areas showed a mild degree of passive congestion and infiltration with round cells.

In other areas, there was slight thickening of the capsule on the surface as well as in some of the portal areas.

Spleen.—The capsule and trabeculae were definitely thickened. The Malpighian bodies showed no change. The sinuses were moderately distended with red blood cells. Numerous areas of necrosis of varying size were scattered throughout the section, the margins of which were not sharply demarcated but tended to fade imperceptibly into the surrounding healthy tissue. A few multi-nucleated giant cells with the nuclei arranged around the periphery of the cytoplasm (Langhans type) were found in the necrotic areas. The majority of giant cells were discrete, but some of them were surrounded by a zone of endothelioid and round cells giving an appearance characteristic of a tuberculous giant-cell system.

Lymph gland.—The capsule was very much thickened. The entire lymph gland was necrosed and there were very few collections of lymphoid cells. Multi-nucleated giant cells, some arranged in follicles, were seen.

Lung.—This did not show any pathological change.

Bacterioscopic examination

In sections of liver, spleen and lymph glands stained with Levaditi's silver impregnation method, no spirochaetes were found, but those stained with Gabbett's modification of Ziehl-Neelsen's method showed the presence of acid-fast organisms in some of the necrotic foci.

Comment

The gross appearances of the liver at first sight suggested secondary carcinomatous growths though there was not the characteristic central umbilication, but on histological examination it

was clear that the lesions were of the nature of an infective granuloma. Even though the firm, elastic, cheesy consistency of the lesions and the infrequency of concentric formation of endothelial cells were suggestive of multiple gummata, the absence of definite fibrous capsule and cicatrices, the negative Wassermann reaction, the presence of Langan's type of giant cells, especially in sections of glands and spleen, were all in favour of tubercle. The view might be held that the peculiar nature of the lesions was due to the coexistence of syphilis and tuberculosis but the negative Wassermann reaction makes this unlikely. However, the definite proof of the lesions being tuberculous in nature was afforded by the demonstration of acid-fast bacilli in sections of the liver, spleen, and lymph gland. But the bacilli being very few in number, they were demonstrated only after careful examination of a number of sections. Histologically, the lesions are unusual, in that giant-cell systems, such as are found in tuberculosis, were rare except in the lymphatic gland and the spleen.

It is generally agreed that tuberculous lesions though conforming in their initial reaction differ considerably in their ultimate results and these variations depend upon the age and susceptibility of the individual, the manner of infection and the virulence and dose of the bacilli. It is also well known that tubercle bacilli not infrequently gain entrance to the blood stream from tuberculous lesions and are carried to distant parts where they lead to the formation of tubercles. It appears, in this case, that the organisms which gained access to the blood stream did not give rise to acute general miliary tuberculosis, either because the patient was relatively immune or because the organisms were of low virulence and their number was small. Variations in the size of the nodules seem to indicate that several distinct emigrations of the tubercle bacilli had occurred.

Summary

A case of tuberculosis of the liver, spleen and lymphatic glands is described. The lesions were peculiar in that the large, solitary tubercles in these organs showed no evidence of softening. Histologically, the follicular arrangement of cells characteristic of tuberculous lesions was not well marked, except in the lymphatic glands. Proliferation of endothelioid cells was not a prominent feature. It is suggested that the infection in this case was caused by an organism of a low grade of virulence, which gained access to the blood stream and produced tumour-like masses in the liver and spleen. Acid-fast bacilli were found in sections of the affected organs.

In conclusion, we have to thank Dr. H. S. Hensman, L.R.C.P., M.P.C., Superintendent of the Mental Hospital, Madras, for furnishing the clinical details.

THE INCIDENCE OF PORTAL CIRRHOSIS OF THE LIVER IN VIZAGAPATAM, BASED ON A CRITICAL STUDY OF AUTOPSY RECORDS AND OBSERVATIONS

By RAO BAHADUR T. S. TIRUMURTI, B.A., M.B.,
C.M., D.T.M. & H. (Lond.)

Professor of Pathology, Medical College, Vizagapatam
and

M. V. RADHAKRISHNA RAO, M.B., B.S.

Research Fellow, Andhra University

(From the Department of Pathology, Medical College, Vizagapatam)

We have shown in our previous communications (Tirumurti and Radhakrishna Rao, 1932; Radhakrishna Rao, 1932 and 1933) that portal cirrhosis is the commonest cause of 'decompensated cirrhosis' of the liver in Vizagapatam. In this short paper, we wish to discuss the incidence of portal cirrhosis of the liver in detail.

In a series of 535 autopsies performed in the King George's Medical College Hospital, Vizagapatam, there were 50 cases (9.3 per cent) of cirrhosis of the liver. The material in this paper is based on a critical study of the autopsy findings in these 50 cases.

The causes of cirrhosis of the liver in the 50 cases under discussion are given in the table.

It will thus be seen from the table that, out of the 50 cases, 'decompensated cirrhosis' was present in 40 (80 per cent) while in 10 (20 per cent) ascites was not present. Coarsely nodular cirrhosis of the Laennec's type was found in 26 cases. In 3 cases in this series the portal cirrhosis was a terminal complication of primary splenic anaemia (so-called Banti's disease) while in the rest (23 cases) the portal cirrhosis was primary, with no definite evidence to account for its causation. The diagnosis was made only post mortem in both cases of portal cirrhosis without ascites. The liver was much smaller than normal in all cases of decompensated portal cirrhosis. It was much enlarged in one case of portal cirrhosis without ascites, and the patient died suddenly after an epileptiform fit, while he was undergoing anti-syphilitic treatment for gumma of the floor of the mouth. As pointed out by Rolleston and McNee (1929), 'the liver is larger in cases of cirrhosis in which the disease is latent, and death occurs from some independent cause, than in patients dying directly from cirrhosis'.

The pathological appearances—macroscopic and microscopic—of the liver in most of the cases of decompensated portal cirrhosis were those of the usual 'hob-nailed' type, but in a few cases, the liver was very coarsely nodular, suggesting 'nodular hyperplasia' (Rolleston and McNee, 1929). The hyperplastic nodules were so big as to resemble tumour growth, and were deeply bile stained. In the absence of definite

Table showing the cause of cirrhosis of the liver in 50 cases

(From a series of 535 autopsies)

Serial number	Cause of cirrhosis	DECOMPENSATED CIRRHOSIS		COMPENSATED CIRRHOSIS		Total number of cases	Total percentage
		Number of cases	Percentage	Number of cases	Percentage		
1	Portal cirrhosis ..	23	46	2	4	25	50
2	Syphilitic cirrhosis ..	5	10	1	2	6	12
3	Infantile biliary cirrhosis.	2	4	2	4
4	Hypertrophic biliary cirrhosis.	2	4	1	2	3	6
5	Perihepatitis and capsular cirrhosis.	1	2	1	2	2	4
6	Associated with malignant disease (primary or secondary) of the liver.	3	6	3	6	6	12
7	Associated with hydatid cyst of the liver.	1	2	1	2
8	Associated with abscesses of the liver.	2	4	2	4
9	Primary splenic anaemia	3	6	3	6

histories in these cases, it is difficult to state correctly whether the 'nodular hyperplasia' is secondary to primary portal cirrhosis, or whether 'nodular hyperplasia' and portal cirrhosis are both sequelæ to subacute hepatic necrosis (the 'toxic cirrhosis' of Mallory, 1911). The microscopical examination of the liver showed marked fibrosis of irregular distribution separating 'adenomatoid' areas of liver cells. The original structure was completely lost in most of the lobules which showed atrophy or degeneration of the liver cells in many places.

Decompensated portal cirrhosis is also seen in children. In one case, the patient was aged about 9 years and showed all the signs and symptoms of portal obstruction during life. At autopsy, the liver was found to be finely granular on the surface and on section, and was deeply bile stained; the left lobe of the liver was markedly contracted, nothing but a small tongue-like process remaining. Microscopically, the appearances were those of typical multilobular cirrhosis. Though the clinical and serological evidences were more in favour of congenital syphilis, the naked-eye and microscopic appearances of the liver were only those of multilobular cirrhosis. Multilobular cirrhosis in children with congenital syphilis has been described (Rolleston and McNee, 1929) and is considered to be probably due to 'some vulnerability or diminished resistance of the liver' left behind after the absorption of the intercellular cirrhosis, predisposing to the disease.

On going through the case-histories of these patients with decompensated portal cirrhosis, we were surprised to find that there was no habit of drinking pure alcohol in any of them. A few patients gave a history of drinking toddy

or arrack, but only in small quantities occasionally, and these cannot therefore be considered to be the chief ætiological factors even in these few cases. The pathological appearances of the liver in these cases are very suggestive of 'toxic cirrhosis' in the sense of Mallory (1911), due to repeated attacks of subacute hepatic necrosis caused by some toxic or toxoinfectious process, the nature of which remains to be determined. The results of the clinical investigation into this type of cases (non-alcoholic type of decompensated portal cirrhosis) are given in detail in a separate paper by the junior author (Radhakrishna Rao, 1933).

In a previous paper (Tirumurti and Radhakrishna Rao, 1933) we have discussed in detail the association of splenomegaly with this type of cirrhosis of the liver.

Varying degrees of fibrosis of the liver were found in malignant disease (primary or secondary) in 6 cases, abscesses in 2, and hydatid cyst in one.

The appearances of the liver in the other cases of cirrhosis do not require special mention.

Summary

A critical study of the recorded observations on autopsies performed in the King George's Medical College Hospital, Vizagapatam, show that the incidence of portal cirrhosis of the liver is rather high (56.0 per cent of all cases of cirrhosis of the liver) in this part of India. Primary splenic anaemia was the cause of portal cirrhosis in a few cases (6 per cent), while in the rest (50 per cent) the causation is far from clear. The pathological appearances of the liver in these cases are described, and it is shown

that in a few cases 'nodular hyperplasia' was seen. Alcohol does not play any part in the ætiology of the disease which is probably of the nature of a 'toxic cirrhosis' (Mallory) due to repeated attacks of subacute hepatic necrosis, caused by some toxic or toxic-infectious process, the nature of which remains to be determined.

CONSTANTS OF COW MILK

By B. B. BRAHMACHARI, D.P.H.

Director of Public Health Laboratory, Bengal

THE standards prescribed for the values of the constants of cow milk under the Acts of the different provinces of India are as follows:—

Act	Specific gravity at 15.5°C.	Milk fat	Milk solids not milk fat	Lactose
Bengal Food Adulteration Act	1028—1030	3.5	8.5	4.4
Calcutta Municipal Act	1028—1030	3.5	8.5	4.4
The United Provinces Prevention of Adulteration Act	1028—1030	3.5	8.5	4.0
Assam Municipal Act	1028—1032	3.5	8.5	..
Bombay Prevention of Adulteration Act	3.5	8.5	..
Madras Prevention of Adulteration Act	3.0	8.5	..
Bihar and Orissa Food Adulteration Act	3.0	8.5	..
The Central Provinces Prevention of Adulteration Act	3.0	8.5	..
The Punjab Pure Food Act	3.5	8.0	..

The Madras Act has also standardized the value of proteins of the cow milk as nitrogen at 0.5 per cent and that of dirt in it at 5 per 100,000 by volume.

It may be remembered here that the standards fixed in England by the Ministry of Agriculture and Fisheries by their Sale of Milk Regulation, 1901, are 3 per cent for milk and 8.5 per cent for milk solids other than milk fat. So the standard prescribed in India for the milk solids other than fat is the same as in England, except in the Punjab where it is lower and that for milk fat is higher in 6 of the provinces but the same in the remaining three, namely, Madras, Bihar and Orissa and the Central Provinces.

We examined 88 samples of pure milk, each sample drawn from a single cow. Two of these samples appeared to be abnormal, the milk solids other than fat in them were 5.9 and 11.5 per cent, respectively; the values of their other constants were:—

Specific gravity at 15.5°C. ..	1021.0	1032.0
Fat	6.5	7.1
Protein	2.1	4.0
Lactose	3.0	6.7
Ash	0.68	0.80

Rejecting these two, we had altogether 86 samples. The results of their analyses are shown in the following table; the figures are the percentage values of the constants. The table also compares these results with those of 643 cows in Scotland given in Currie's *Textbook of Hygiene* (1930).

(a) The probable error of the average, i.e., $0.6745 \times \sqrt{\frac{\text{standard deviation}}{\text{number of samples}}}$ is negligible in respect of all the constants. So though the number of samples is only 86, the group is quite representative of the cow milk in Calcutta.

(b) This is further corroborated by the fact, as will be seen below, that the analyses for fat, solids-not-fat, ash and specific gravity of cow milk supplied to the hospital of the Calcutta School of Tropical Medicine from day to day for a long period have given the same result.

(c) Lastly, it will be interesting to see that the values as well as the relative variability of

the constants of our 86 Calcutta samples agree fairly closely with those of the milk of the 643 Scotch cows; that the average fat values of the milk of our cows is decidedly higher is consonant with the fact that the yield of animals poor in quantity is richer in quality, especially in fat.

We noticed also that, taking the figure for ash in any sample as unity, the quantity of its other two non-fatty constituents were as follows:

Lactose from 5.4 to 8.0 with a mean of 6.8 ± 1.2
Protein from 3.5 to 5.9 with a mean of 4.8 ± 1.1

Therefore the ratio, lactose : protein : ash = 13.6 : 9.6 : 2, practically the same as found by Vieth in European milk, which is 13 : 9 : 2.

Constants	Range	Average	Standard deviation	Relative variability	CONSTANTS OF MILK OF 643 COWS IN SCOTLAND	
					Average	Relative variability
Specific gravity at 15.5°C. ..	1026.4 — 1036	1031.5	1.46	4.02 *	31.5	4.96
Fat	1.9 — 10.6	5.1	1.3	25.5	3.95	19.75
Solids-not-fat	8.0 — 10.8	9.3	0.5	5.4	8.80	5.02
Ash	0.4 — 0.85	0.74	0.05	7.3	0.70	7.21
Lactose	3.72 — 5.72	5.0	0.39	7.8	4.53	8.01
Protein (N×6.38) ..	2.46 — 4.27	3.5	0.39	11.1	3.19	12.22
					(N=0.5)	

* The figure for the specific gravity being taken as 31.5 instead of 1031.5.

Our results might be compared with those of Drs. Dutta and Ghosh of the Calcutta Municipality, and of Crippen (Simpson, 1908); the values obtained by Crippen were slightly less than ours, and in those of Dutta and Ghosh the averages of protein and lactose were both 4.4, and of ash 0.7 and over in all samples.

Constants of cow milk from dairies.—The milk supplied by the milkman is, as a rule, a mixture of the yield of a number of cows and not that of a single cow. As mentioned above we have to examine the daily supplies of milk to the hospital of the Calcutta School of Tropical Medicine. For routine work, we examine them only for their specific gravity, milk fat and milk solids-not-fat. But we made a special study of the milk which was supplied from the 30th October, 1924, to the 10th March, 1927, and

for the purpose included also the estimation of ash in the 1,191 samples of this period. Four showed departure from the rest, the constants in them were:—

Sample	Specific gravity at 15.5°C.	Fat	Solids-not-fat	Ash
1	1025.5	6.0	7.71	0.67
2	1029.0	5.0	8.4	0.57
3	1027.0	4.5	7.8	0.64
4	1032.0	4.8	14.1	0.76

In no. 2 the ash was below 0.6 per cent. The solids-not-fat was below 8.0 per cent in nos. 1 and 3, and above 10.0 per cent in no. 4. The values of the constants in the remaining 1,187 samples were as below:—

Constants	Observed range	Average	Standard deviation	Relative variability
Specific gravity at 15.5°C. ..	1025.5 — 1033.5	1031.4	0.81	2.58 *
Solids-not-fat	8.0 — 10.0	9.02	0.27	2.99
Fat	4.0 — 7.0	5.03	0.46	9.14
Ash	0.60 — 0.80	0.72	0.03	4.16

* Calculated on 31.4 as specific gravity.

The fat was below 4.0 per cent in only 1 out of these 1,187 samples, which is in less than one per thousand, and even in this it was 3.9. In 36 (i.e., 3.0 per cent) of the samples the solids-not-fat was below 8.5 per cent. The number of samples which gave ash at less than 0.66 per cent was also 3.5. In only 11 (i.e., 0.8 per cent) of the samples was the specific gravity less than 1028.

Constants of cow milk according to period of lactation.—Out of the 88 cows, the milk of which we examined separately, we obtained information about the period of lactation of 77. The average values of the constants of these samples according to the period of lactation were found to be as in the following table:—

Period of lactation	Number of samples	Specific gravity at 15.5°C.	Fat	Protein	Lactose	Ash
Under 1 month	3	1033.5	3.8	3.6	5.0	0.79
1 month	5	1031.6	4.4	3.1	5.2	0.69
2 months	12	1031.2	4.3	3.3	5.1	0.70
3 "	11	1032.4	5.4	3.4	5.1	0.72
4 "	11	1031.6	5.2	3.4	5.0	0.73
5 "	11	1031.7	5.5	3.4	5.5	0.77
6 "	11	1031.2	5.3	3.4	4.8	0.76
7 "	2	1028.0	5.6	3.5	4.6	0.73
8 "	6	1030.7	5.2	3.6	4.6	0.73
9 " and over	5	1031.9	5.4	3.8	4.9	0.73

The number of samples of the different periods is very small. Still, without any suggestion at generalization from them, we may notice, (a) that the amount of fat increases after the first three months, so that in the mixed milk of all subsequent months it is always over 5 per cent, and that even in the second month it is over 4 per cent, (b) that the protein in all these groups is over 3 per cent, or in terms of nitrogen over 0.47 per cent, (c) that lactose tends to decrease with age, but in no group is it less than 4.5 per cent, and (d) that in no group is the ash less than 0.7 per cent.

Constants of milk of individual cows.—While the milk of commerce is, as a rule, a mixture of the products of a number of cows, still the sale of milk of single cows is by no means rare. We may refer back to the first paragraph for the standards for the constants which have been fixed in the different provinces. We have already seen the range of the values of these constants in the milk of the 86 cows analysed by us. The number of those samples, the constants of which were below these standards, are shown in the following table :—

Constants	Standard values	SAMPLES WITH LOWER VALUE	
		Number of samples	Percentage to total number of samples
Specific gravity at 15.5°C.	1028	3	3.5
Fat ..	4.0	16	18.6
	3.5	9	10.5
	3.0	2	2.3
Solids-not-fat	8.5	2	2.3
Lactose ..	4.4	4	4.6
	4.0	2	2.3
Protein ..	3.1	11	12.8
	(N=0.5)		
	2.5	Nil	Nil
	(N=0.4)		
Ash ..	0.66	2	2.3

Standard.—(1) *Solids-not-fat*: Richmond (1920) recommends a multiple standard of 8.5 per cent of solids-not-fat, 4.5 per cent of milk sugar, 0.50 per cent of total nitrogen, and 0.70 per cent of ash for judging whether a milk is of genuine composition or not. We have seen above that the relative variability of the solids-not-fat is only 5.4 and those of ash and lactose are only a little higher, viz, 7.3 and 7.7 respectively; we see also that the percentage of samples which had lower values for these three constants than 8.5, 0.66 and 4.0, respectively, are only 2.3. The variability of the protein in the milk of our cows is 11.1; the standard for it has been found

by the Madras Act, too, at 0.5 per cent as nitrogen; but we see that this standard would condemn 12.8 per cent of the samples of our genuine milk from separate cows while none of them had the nitrogen at 4.0 per cent or less; 0.45 would be the value which would probably meet our requirement. It follows that the standards should be :—

for solids-not-fat = 8.5, as at present
 „ ash = 0.66
 „ protein = 2.8, or as nitrogen 0.45
 „ lactose = 4.0, or even 4.4 as at present.

We have seen that the ratio lactose : protein : ash = 12.6 : 9.6 : 2. So we must remember that any upsetting of these relations would point to the milk being abnormal.

(2) *Fats*.—The milk fat is much more variable. But, as in no sample of mixed milk was it found to be less than 4 per cent, except in 1 out of the 1,187 samples examined, and even in that it was 3.9 per cent, any milk with less fat may very well be looked upon with suspicion, and, in any case, a milk with less than 3.5 per cent of fat must be presumed as not genuine, the onus of proving such samples to be otherwise resting with the vendor.

(3) *Specific gravity*.—Three out of the 86 samples, i.e., 3.5 per cent of them, had specific gravity below 1028 at 15.5°C. So any milk with a lower specific gravity is suspicious, while if the specific gravity is 1025, or less, it is certainly adulterated.

For this work, I am indebted to my assistant analyst, Mr. S. K. Banerjee, B.Sc., who helped me by analysing the milk of the single cows, as well as those of the School of Tropical Medicine.

A Mirror of Hospital Practice

SYPHILITIC CIRRHOSIS OF THE LIVER WITH ASCITES IN A CHILD

(REPORT OF A CASE)

By M. V. RADHAKRISHNA RAO, M.B., B.S.

Research Fellow, Andhra University

(From the Department of Pathology, Medical College, and King George Hospital, Vizagapatam)

History.—A Hindu male child aged 3 years and 2 months, belonging to the goldsmith caste, was admitted into the children's ward of the King George Hospital, Vizagapatam, on 5th August, 1931, for swelling of the abdomen of two months' duration. About one year prior

to admission the parents noticed enlargement of the liver and spleen for which various ayurvedic drugs were tried without success. The child's general health was good during the period though it had diarrhoea for about a month prior to admission.

The patient was the sixth child in the family of seven children; the first child died ten days after birth; the fourth and fifth children had enlargement of the liver and spleen, but they improved after treatment. Both the parents appeared healthy and gave no history of previous venereal infection.

The child was fed on breast milk till the end of the 3rd year and it was then supplemented by Nestle's condensed milk and diluted cow's milk. The parents were strict vegetarians in their diet and the same diet was given to the child in small quantities from the end of the sixth month.

Physical examination.—The child appeared to be moderately nourished, the visible mucous membranes were not anemic and there was no jaundice; there was marked oedema of the lower extremities below the knees. There was slight bossing of the frontal prominences and the glands in the posterior triangles of the neck were shotty and elastic on palpation. The child appeared dull and there was difficulty in breathing, on account of the fluid in the abdomen.

The circulatory and respiratory systems were normal except for the pressure effect of the fluid in the abdomen.

The abdomen was markedly distended with free fluid, and prominent and dilated veins were seen over the anterior abdominal wall coursing upwards towards the sides of the chest. The liver, which was palpable (after paracentesis of the abdomen) to about two finger-breadths below the costal margin, was hard, with a finely granular surface and a sharp, hard edge. The spleen was enlarged to three finger-breadths below the costal margin and fairly hard.

Laboratory findings:

(a) **Blood.**—Hæmoglobin, 70 per cent.

Total red cells, 4.95 millions per c.mm.

Total white cells, 4,500 per c.mm.

The blood smear did not show anything abnormal. The coagulation time was 5 minutes and 35 seconds. The formol-gel test was negative in 24 hours. The van den Bergh's reaction was direct, delayed. Hemolysis of red cells (fragility) began in 0.4 per cent saline and was completed in 0.25 per cent saline. The halometer reading of the blood film was 4.6.

The agglutination test with dysenteric organisms was positive for *B. dysenteriae* (Flexner only) in dilutions up to 1 in 128. The Wassermann reaction was moderately positive.

Widal's hæmolytic crisis showed that the liver function was impaired.

W. B. C. count before giving milk	4,500 per c.mm.
W. B. C. count 20 minutes after giving milk	5,200 "
W. B. C. count 40 minutes after giving milk	5,500 "
Rise of W. B. C.	1,000 "

(b) **Urine.**—The physical, chemical and microscopic examination of the urine did not show anything abnormal except that it was very pale and opalescent, with a specific gravity of 1002. Urea concentration test showed that the kidneys were functioning normally.

(c) **Motions:** were greenish-yellow and well formed. Microscopic examination of the faeces showed nothing abnormal.

(d) **Ascitic fluid:** was straw-coloured and clear, with a specific gravity of 1005. The protein content of the fluid was 0.09 gramme per cent and the cell count was 478 per c.mm. The cells were mostly lymphocytes with a few endothelial cells.

The Wassermann reaction of the fluid was strongly positive, while the agglutination test with dysenteric organisms was negative.

On culture, only staphylococci were grown, this was probably the result of contamination.

The guinea-pig into which 20 c.cm. of the ascitic fluid was injected intraperitoneally, died about 7 months after inoculation and on post-mortem examination showed only congestion of all the internal organs.

Progress and treatment.—The patient was afebrile during his stay in the hospital. He was treated with

iodides, inunctions of mercury, and later, intramuscular injections of bismuth. In spite of the administration of diuretics and intramuscular injections of salyrgan, the fluid in the abdomen did not show any diminution, thereby necessitating paracentesis (which was done four times during a stay of 20 days in the hospital). When the patient was discharged from the hospital on 24th August, 1931, his general condition was slightly improved, but the ascites was still a troublesome feature. Unfortunately the patient's subsequent history could not be traced, as the parents did not report again.

Comment.—In this case, the diagnosis of syphilitic cirrhosis of the liver is quite evident from the physical examination, family history and the positive Wassermann reactions of the blood and ascitic fluid. The family history that

the fourth and fifth children had similar enlargements of the liver and spleen is suggestive of this case being one of infantile biliary cirrhosis, but the age, absence of jaundice and the positive Wassermann reactions of both the blood and ascitic fluid are against such a diagnosis. In infantile biliary cirrhosis, the jaundice is generally intense by the time the patient develops ascites.

The effect of antisyphilitic treatment could not be studied in this case, as the patient could not be traced subsequent to discharge from the hospital.

In this case, in addition to the usual signs and symptoms of syphilitic cirrhosis of the liver in children, that of portal obstruction was very marked and constituted the predominating sign.

I wish to express my thanks to Dr. G. Dinker Rao, first physician, and to Dr. P. Kutumbaiah, second physician, King George Hospital, Vizagapatam, for permission to publish these case notes, and to Dr. P. Kesavaswamy, radiologist of the hospital, for the photograph.

A LARGE FIBRO-LIPOMA

By B. L. SAHI, M.B., B.S.

Chief Medical Officer, Rajgarh State, Central India
and

B. S. SAXENA, L.C.P. & S.

Sub-Assistant Surgeon, Rajgarh State, Central India

KALOO, Hindu male of the village Borkheri, Tehsil Iklehra, Kotah State, 55 years of age,

was admitted to the Imprey Hospital, Rajgarh State, on 5th February, 1933.

Fourteen years ago, a small lump appeared in his right axilla which steadily grew to the present size. The tumour remained painless and, but for its huge bulk, the patient was none the worse for it.

In length the tumour was 21 inches; in circumference 29 inches. The right nipple had been drawn away from the body and occupied almost the centre of the growth. The consistency was plastic and nowhere cystic. In two places the tumour showed hard nodules, and in three places small ulcerated areas, due to friction with hard objects during sleep. The skin was movable all over it and the veins prominent—one big vein is visible in the photograph. The supraclavicular, infraclavicular and axillary glands were not enlarged.

The ribs and spine were bent towards the right side. In walking about, the patient experienced great difficulty. He was much emaciated, and after 10 days free dieting he weighed 118 pounds.

The tumour was removed under general anaesthesia. It weighed 24 pounds and the patient made an uneventful recovery.

There is no record in the literature available to me of a larger tumour than this.

RADICAL CURE FOR INGUINAL HERNIA UNDER LOCAL ANÆSTHESIA*

By ALLIBHAI D. PATEL, S.M.S.

Medical Officer In-Charge, Dispensary, Nandurbar, W. K.

A MOHAMEDAN male, aged about 40 years, was admitted into the dispensary with a right-sided inguinal hernia, of about three years' duration. He was prepared for operation next day.

On the morning of the operation, he was given 1/6th grain of morphia hypodermically after an enema and the same dose was repeated half an hour before the operation.

Four ounces of novocaine solution of a strength of four grains to the ounce was prepared. After boiling for ten minutes two drops of adrenalin solution 1/1000, to each ounce of the solution, was added. An ordinary 10-c.cm. Record syringe with finger bars, two local-anæsthesia needles and one hypodermic needle for intramuscular injection, were used.

The initial intradermal skin weal was made one inch external to and a little above the internal abdominal ring, and from there the subdermal infiltration was made towards and a little above the external abdominal ring and further, towards the upper part of the scrotum. Forty cubic centimetres of the solution were injected here with an ordinary local-anæsthesia needle, which was flexible and three inches long. Another intradermal skin weal was made in the line of and about an inch internal to the anterior superior spine. Here the intramuscular, short and stiff, needle was used. The needle to the length of about three-fourths of an inch was inserted perpendicularly so as to pierce the aponeurosis of the external oblique, which is the anatomical position of the two nerves, ilio-inguinal and ilio-hypogastric. About 30 c.cm. of the solution were allowed to run in slowly so as to saturate these two nerves. The point of the needle was kept moving in all directions. The needle was then gently pushed onwards to infiltrate the peritoneum and when it had gone in just a little distance the patient immediately complained of hyperæsthesia up to the lower part of the thorax, indicating that the needle point had touched some branch of the

* Rearranged by Editor.

twelfth thoracic nerve. The needle was pushed a little further onwards and then directed transversely towards Poupart's ligament, allowing the solution to run slowly all the time. In all 80 c.cm. of the solution was used. The remainder was kept for further use if required.

The anaesthesia appeared to be quite successful as the patient felt no pain throughout the operation, all that he described were sensations of stretching and pulling. It should be mentioned, however, that the hernia was a very simple and straightforward one.

One hour after the operation the patient perspired profusely and was a little bit nervous. A dose of stimulating mixture was given to him.

The patient had no post-operative nausea or vomiting and he was allowed to have both solid and liquid food from the day of the operation.

There was retention of urine which required catheterization, once only, after the operation.

His bowels did not move for three days. One ounce of castor oil was given on the fourth day and after that his bowels were regular.

The dressing was removed on the tenth day for the first time and stitches taken out. The recovery was uneventful and the patient was discharged on the twenty-third day after admission.

A CASE OF HYDROPHOBIA AFTER PREVENTIVE INOCULATION

By **RABINDRA CHANDRA DAS GUPTA, M.D.**
*Medical Officer, Law Estate Charitable Dispensary,
Morrelganj*

B. T., a Gurkha, had been bitten by a rabid dog in several places on his hand and leg on the 17th March, 1933.

He came at once to the local dispensary where his wounds were attended to and cauterized with strong carbolic acid. He was sent to the Tropical School at Calcutta (Pasteur Institute) on the next day. He reached Calcutta on the 19th March and treatment was begun on the day following. There he received a full course of inoculations and returned to Morrelganj on the 4th April, 1933, apparently cured. He resumed his duties and for the next seven months he was all right. But on the 4th November last he had an attack of fever in the night. I was called in to see him the next morning. I found his temperature to be 101°F. He had pains about his whole body, and a severe headache. His eyes were bright red. His bowels had not moved for the last two days. I prescribed an alkaline mixture with magnesium sulphate and potassium bromide. At noon of the same day, I was called again as the patient was very excited and restless and shuddered at the sight of water. He presented all the typical symptoms and signs of hydrophobia.

He was sent to Calcutta on the evening of the same day, but he died on the way on the next morning at about 7 a.m.

The interesting feature of this case is that the man had a full course of preventive inoculations soon after the bites, yet he died of hydrophobia after seven months.

(Note.—There are certain points in this case that call for comment. The writer does not state whether or not there was any evidence that the patient had been bitten subsequently to receiving treatment. Deaths later than three months after treatment are extremely rare, and the League of Nations Health Organization have laid down six months as the safe period. In

the whole history of Pasteur Institute treatment only very few instances of such late development of symptoms have been reported. Dr. M. J. Nicholas, officer in charge of the Pasteur Institute at the School of Tropical Medicine, very kindly looked up the records of this man; the following notes are extracted therefrom:—

An unprovoked attack was made on the patient by a dog that was apparently rabid and was afterwards killed; he had 11 bites on his hands and arms, six of which were deep; he received a full course of 14 days' treatment; his death had not been reported.

We take this opportunity of pointing out that it is of the utmost importance that, whenever a patient who has received anti-rabic treatment dies, the fact should be reported to the officer in charge of the Pasteur Institute where he received treatment; the records collected in these institutions are of great scientific value, as it is on them that decisions regarding the efficacy of the different forms of treatment are based.—EDITOR, I. M. G.)

UNSUSPECTED CHOLECYSTITIS

By **M. N. SARDANA, M.D.B.S., L.R.C.P., M.R.C.S., D.T.M.**
D.O.M.S., F.R.F.P.S.
Chief Medical Officer, Bharatpur State

A HINDU woman aged about twenty-six years asked me to examine her while she was in hospital with her child who was being treated.

A slightly movable pear-shaped tumour about the size of the closed fist was present in the right lumbar region. This had been present for three or four years but had caused no discomfort or pain.

After a considerable amount of questioning the woman gave an indefinite account of attacks of pain, possibly of the nature of renal colic. Her urine was normal and exertion pycnography revealed no abnormality of the kidneys. After brisk purging the tumour was found to be freely movable from one side of the abdomen to the other.

A provisional diagnosis of mesenteric tumour was arrived at and laparotomy decided upon. On opening the abdomen by a right paramedian incision, the mass was felt in the right lumbar region. It was freely mobile and was brought out through the abdominal wound. It was found to be a greatly distended gall-bladder, hanging from the under surface of the liver. A stone was felt embedded at the junction of the cystic duct. The bladder was tapped and about 6 ounces of mucus-like fluid removed. Four stones were removed from the fundus. The one in the cystic duct could not be removed except by cutting directly over it. The gall-bladder was then excised, the common bile duct probed and the laparotomy wound closed. A stab puncture was made in the right loin for drainage.

The drainage tube was removed after 48 hours.

The patient made an uninterrupted recovery except for an attack of malaria on the 8th day after the operation.

The case was interesting on account of the absence of any symptoms.

I have to thank the subordinate staff of the Victoria Hospital, Bharatpur, for their co-operation in the investigation and treatment of the case.

SYPHILITIC CIRRHOSIS OF THE LIVER ASSOCIATED WITH GLYCOSURIA IN A CHILD

(REPORT OF A CASE)

By M. V. RADHAKRISHNA RAO, M.B., B.S.

Research Fellow, Andhra University

(From the Department of Pathology, Medical College,
and King George Hospital, Vizagapatam)

History.—A Hindu male child, aged 20 months, was admitted into the children's ward of the King George Hospital, Vizagapatam, with a swelling of two months' duration in the upper part of the abdomen.

The child was healthy and active till the end of the 18th month, after which it had fever for about a fortnight and the mother noticed that the upper part of the right side of the abdomen was prominent and hard. The child gradually lost weight from that time onwards.

The patient was the only child of the parents. The father of the child was a ryot by occupation and gave no history of any venereal disease. The mother was in good health and showed no clinical manifestations of syphilis and gave no history of abortions or miscarriages.

The child was fed on breast milk supplemented with diluted cow's milk from the end of the 3rd month. It was given small quantities of rice from the end of the 18th month; sweets and biscuits were given to prevent it from crying.

Physical examination.—The child was moderately nourished, peevish and irritable. There was no oedema in any part of the body. All the visible mucous membranes were normal, except that there was a slight icteric tint of the bulbar conjunctiva. The skin was dry and it lay in folds over the thighs and buttocks. The posterior cervical, inguinal and epitrochlear glands were enlarged and shotty. The head was dolichocephalic, with slight bossing of the frontal eminences. Dentition was normal; temperature, pulse and respiration were normal.

The chest was symmetrical and normal in shape. The bases of both lungs showed diminished resonance and on auscultation a few râles and ronchi were heard. The first sound of the heart was replaced by a systolic murmur in all the areas and the second sound was reduplicated at the base. The pulse was regular, slightly rapid, with good volume and tension.

The upper part of the right side of the abdomen was prominent and a few veins were seen over it. The liver was enlarged to a hand's breadth below the costal margin, hard and finely granular on its surface; the lower edge was sharp and hard. Also the spleen was enlarged to a hand's breadth below the costal margin and was hard. There was no ascites. The appetite was voracious and the bowels were regular.

The epiphyseal ends of the long bones were normal and showed no enlargement. All the deep reflexes were normal.

Laboratory findings:

(a) **Blood.**—The blood-picture was normal except for slight anisocytosis. The van den Bergh's reaction was direct, biphasic. The agglutination test with dysenteric organisms was negative. The Wassermann reaction of the blood was weakly positive. The hemolysis of the red cells (fragility) began in 0.4 per cent saline and completed in 0.3 per cent saline.

(b) **Urine.**—This was clear, straw-coloured, strongly acid in reaction and showed a specific gravity of 1004. Albumin, phosphates, urates, bile salts, bile pigments, indican, urobilinogen and urobilin were absent. The urine reduced Benedict's solution and on quantitative estimation the sugar content was 0.43 per cent. The nature of the reducing sugar was found to be glucose. There was no acetone in the urine.

Microscopic examination of the urine showed no cells, casts or crystals.

(c) **Fæces.**—The stools were solid and brownish in colour. Microscopical examination showed round-worm and whip-worm ova; no amœbic cysts or Charcot-Leyden crystals were found. The biochemical examination for the fat content of the fæces gave the following results:—

Total fat, 52.00 grams per 100 grams by weight of dried fæces.

Unsoaped fat, 24.00 grams per 100 grams by weight of dried fæces.

Free fatty acids, 22.43 grams per 100 grams by weight of dried fæces.

Neutral fat, 1.57 grams per 100 grams by weight of dried fæces.

Combined fatty acids, 28.00 grams per 100 grams by weight of dried fæces.

Progress and treatment.—The patient was given potassium iodide internally, together with daily inunctions of unguentum hydrargyri. He was discharged from the hospital at the request of the parents after a stay of a fortnight, during which period he showed no improvement. The parents were advised to bring the child to the out-patient department for further treatment, but, as they did not report again, the further history could not be traced.

Comment.—The clinical picture in this case is fairly typical of congenital syphilis. The child was very troublesome and a thorough investigation could not be carried out. It is therefore difficult to explain the cause of the glycosuria. The total fat content of the fæces is increased; this is due to an increase in the fatty-acid fraction, showing that there is defective absorption of fats. The pancreatic function, so far as the fat digestion is concerned, appears to be good. Though the liver plays an important rôle in the carbohydrate metabolism of the body, glycosuria of hepatic origin is very rare in hepatic disorders. In the absence of a complete investigation it is difficult to say whether the glycosuria in this case is of hepatic or pancreatic origin, though the laboratory findings are more in favour of the former than of the latter.

I wish to express my thanks to Dr. G. Dinker Rao, first physician, and to Dr. P. Kutumbaiah, second physician, King George Hospital, Vizagapatam, for permission to publish these case notes.

A CASE OF RESISTANT PROTOZOAL DYSENTERY

By R. M. LLOYD STILL, M.R.C.S., L.R.C.P.
CAPTAIN, I.M.S.

and

JEMADAR MANOHAR LAL DANG, D.T.M., I.M.D.
(From the Indian Military Hospital, Dehra Dun)

A PATIENT aged 22 years of 19th Mountain Battery, Royal Artillery, Dehra Dun, was admitted to the Indian Military Hospital, Dehra Dun, on the 5th August, 1933, with the following complaints:—

Frequency of stools containing blood and mucus, abdominal discomfort, slight tenesmus, no vomiting or fever. Duration 3 days.

History.—Patient states that he commenced to have abdominal pain on the afternoon of the 3rd August, and passed a loose stool at 4 p.m. without any blood or mucus. He did not feel sick and was at work till the next morning when he reported sick and was given palliative treatment consisting of a carminative mixture and saline. On the morning of the 5th August, his symptoms became worse and he was admitted to hospital.

Previous history.—Patient does not give any history of dysentery prior to this attack.

Condition on admission.—He is a thin, spare and slightly anæmic man, complains of pain in abdomen along colon, tenderness at hepatic and splenic flexures and a little at cæcum. Stools number 6 to 8 in 24 hours with slight griping. No fever and pulse rate 74 beats per minute, no enlargement of spleen or liver. Other symptoms:—Nothing abnormal could be elicited.

Stool examination.—Quantity about 2 ounces, smell offensive, blood and slight mucus with faecal matter. Reaction neutral.

Microscopic examination.—

Exudate—nil.

Numerous red blood cells.

Vegetative *Entamoeba histolytica* seen in large numbers.

Culture.—No organism of the dysentery group isolated.

Treatment.—(1) Castor oil and tincture of opium.

(2) Absolute rest in bed and hot water bottle to abdomen.

(3) Emetine injections, one grain daily.

(4) Bismuth carbonate, one drachm three times a day.

Progress.—On the 18th August stools formed, course of emetine completed and patient convalescent, placed on light diet.

On the 20th August, patient passed considerable quantity of blood in stools, no mucus.

Examination of stools.—

Exudate—nil.

Red corpuscles—numerous.

Pus cells—nil.

No vegetative amœbæ or cysts seen.

Culture.—No organism of dysentery isolated.

Treatment.—(1) Put on 'No diet'.

(2) One ounce of castor oil.

(3) Saline mixture, two drachms every two hours.

On the 22nd August number of stools 10, very offensive and containing trace of blood.

Microscopic.—Reaction—alkaline.

Few pus cells present.

Red corpuscles present.

Exudate—indefinite.

No vegetative amœbæ or cysts seen.

Culture.—No organism of dysentery group isolated.

24th August.—Patient complains of pain and heaviness in abdomen, could not sleep at night. Stools very loose, 16 to 20 in number, containing mucus and blood, looking very ill.

Stool examination.—Large number of vegetative *E. histolytica* seen.

Treatment.—(1) Yatren pills. One three times a day.

(2) Rectal lavage with 200 c.cm. of two per cent solution of Yatren once daily preceded by a wash out with sodium bicarbonate solution.

26th August.—Condition of stools improved. Alkaline lavage brought away a considerable quantity of mucus in flakes; pain much relieved.

1st September.—In spite of yatren irrigation, mucus still persisting; no vegetative amœbæ in stools. Patient still feeling very weak, has no appetite and refuses to take milk. Yatren lavage replaced by eusol solution.

3rd September.—No abdominal symptoms but generalized pain in body and limbs, but no swelling in any joint. Patient is anæmic and still has no appetite, stools loose, decreased in number, slight mucus but no blood.

9th September.—Condition much improved, stools clear, no mucus or blood, patient very weak, no appetite, general pain much less.

Treatment.—(1) All treatment stopped.

(2) Stovarsol 1 tablet 4 grs. once daily for 12 days.

16th September.—Stools well formed, of yellow colour. No constipation, appetite much improved, no abdominal complaint.

24th September.—Patient is now in convalescent stage with general health improving daily.

Microscopic examination of stools.—No vegetative *Entamoeba histolytica* or cysts seen on repeated examinations.

This case presents certain unusual features and is therefore of interest. After apparent cure with emetine and bismuth there was a relapse and the patient became seriously ill. Yatren was used both by the mouth and per rectum for the treatment of the relapse with apparent benefit, but the patient still passed a considerable amount of mucus until the substitution of eusol for yatren as a rectal lavage finally cleared up this condition, and a course of stovarsol, after cure was complete, greatly improved the patient's general condition.

We are greatly indebted to Lieut.-Colonel D. C. V. Fitzgerald, M.C., I.M.S., Officer Commanding, Indian Military Hospital, Dehra Dun, for permission to publish this case and for his advice.

AN OVARIAN DERMOID WITH TWISTED PEDICLE

By T. C. GOPALAN, L.M.P.

Sub-Assistant Surgeon, Civil Hospital, Syriam

A BURMESE female, aged 14, was admitted into the Civil Hospital, Syriam, on 17th October, 1933, for treatment of a tumour protruding from the anus. She stated that she had been passing blood and mucus for about four days and in the morning a lump had come out while at stool. She made no complaint of any abdominal pain nor of any vomiting.

On examination a tumour roughly circular and about the size of a cricket ball on which there was a tuft of hair about 4 inches long, was seen protruding from the anus. On rectal examination a pedicle about the thickness of a finger was felt. It was stretched and its attachment could not be reached. Both tumour and pedicle were reddish-black in colour giving the appearance of strangulation.

General condition.—Temperature was 101°F. otherwise her general condition appeared normal and there was no tenderness or rigidity of the abdomen.

On the morning of the 19th the tumour was examined under spinal anaesthesia by the civil surgeon, Syriam, and as even then the attachment of the pedicle could

not be located, it was ligated and the tumour removed. It was noticed that after removal of the tumour the stump receded and could not be felt. About 6 hours later the patient developed signs of severe shock and, in spite of all treatment, she died at midnight.

A post-mortem examination revealed the presence of a small amount of pus in the pelvis. The gangrenous stump was found to be attached to the left ovary and was inside the peritoneal cavity. The pouch of Douglas and posterior surface of the uterus formed a pocket with a blackened and gangrenous surface, and on the anterior surface of the rectum, which formed the posterior wall of this cavity, there was a perforation through which the tumour must have been extruded during the muscular efforts at defaecation.

The tumour was in the form of a multilocular cyst containing a dark-coloured fluid and having a thick wall bearing a tuft of hair, pieces of cartilage, and a rudimentary tooth projecting on the outside.

I am indebted to Dr. R. H. Liscombe, the civil surgeon, Syriam, for kindly permitting me to publish the notes of this case.

DATE STONE CAUSING APPENDICITIS

By SATYAPRIYA MOZUMDAR, M.B. (Cal.),
F.R.C.S. (Eng.)

Honorary Surgeon, Purulia Sadar Hospital, Purulia

A young adult was admitted to the hospital with all the signs and symptoms of an acute appendicitis. The duration of the disease was six days before admission. The patient looked ill—but it was difficult to decide whether the abscess was being shut off by nature, and whether by interference we would just disseminate the pus. After 48 hours in the hospital, however, operation was decided upon.

The abdomen was opened by McBurney's incision and anteriorly nothing abnormal was found, the healthy caecum and ileum nicely covering up the abscess behind them. On gently exploring with the fingers behind the caecum after lifting up an adherent loop of ileum, the appendix was found in the retro-caecal position with the tip directed upwards. While exploring the abscess cavity, a little grating substance could be felt. On further investigation, it was found to be a foreign body lying free in the abscess cavity. It was extracted with some difficulty and was found to be a whole date stone not altered by the long process of digestion it had gone through. It was argued that it might be an appendicular concretion but it was definitely proved otherwise.

The perforated stump of the appendix was just ligatured—its thickness was nearly that of the small intestine—nothing else being practicable the abscess cavity was drained.

The patient made an uneventful recovery. On being asked, she could not remember ever having swallowed a date stone—so the interval between this and the onset of the trouble could not be ascertained.

A CASE OF HORNY PAPILLOMA

By D. N. GUPTA

Teacher of Surgery and Deputy Superintendent,
General Hospital, Cuttack

N. L., aged about 60 years, H. M., a cultivator, was admitted into Arrah Sadar Hospital on the 1st February, 1928, for treatment of a horny papilloma.

The horn started as a small, hard and tough warty growth on the right side of the chest a little below the clavicle and close to the anterior fold of the axilla. As the growth increased in size, the patient noticed

horny changes taking place. These changes began at the tip and spread towards the base and at the same time the growth was becoming curved. At the time of admission it was three inches in length and resembled the horn of a goat. There was no specific history.

The man had generalized leucoderma.

The papilloma was removed and healing was uneventful.

The specimen is preserved in the museum of the Cuttack Medical School.

WASTE, WEALTH, AND HEALTH

ENVIRONMENTAL cleanliness in its relationship to either comfort or health must have been a comparatively late development in human history. Not until the easier gregariousness of early human life was abandoned for larger social and communal aggregation with permanent or semi-permanent locations, could the matter have obtruded itself either on man's intelligence or his senses. Such communities further could hardly have existed till the comparatively advanced age when man had become more or less agricultural, and had even begun to domesticate certain species of animals. It is unlikely however that in these early communities environmental or 'district' cleanliness was prompted either by fastidiousness of the senses or by any apprehension of danger to health. It is true that the interests of health are often identical with those of common physical convenience; 'kitchen middens' and the large crude drains and sewers of our earlier and later ancestors were undoubtedly prompted by considerations of the latter nature.

Communal agriculture is probably the oldest of human institutions and had its beginnings in some far-off prehistoric Aryan motherland, from whence it was conveyed and diffused by successive streams of civilizing Aryan migration. Later, it became the land custom throughout Europe, and is eminently still present in India among populations perhaps first in descent from the village communities that invented it.

The discovery, that animal refuse is wealth in agriculture, must also be immensely old and must have led to a much quicker removal of much human and animal refuse that would otherwise have been tolerated in the vicinity of villages. This discovery, ancient as it is, even yet has not given to mankind more than a small share of the benefits that it is capable of yielding. The connections of cleanliness of the surroundings of human communities, with agriculture and food supplies, and with human health, are thus old and intimate. They have been lost sight of at various periods of history and it is part of our present purpose to remind our readers of their fundamental inter-relationship; and in particular to draw attention to the very important work in this connection which has been carried out in India, work which should happily combine the benefits of modern science and the advantages of ancient village life.

Real environmental cleanliness in relation to health began in quite modern times with the

work of the English sanitarians and humanitarians in the early part of the 19th century. The appalling conditions of the industrial revolution led to a belief in the principle that poverty and disease were chiefly the result of bad environment, and led also directly to the establishment of central and local sanitary authorities, specifically created for the purpose of environmental improvement. Rubbish and filth were held to be the direct progenitors of disease and as such became anathema to the newly-created inspector of nuisances and the medical officer of health. The success of this policy appeared to establish the truth of the principle. So great was the belief in the generation of disease by filth, that no less a personage than Miss Florence Nightingale is said to have been able to distinguish by the appearance and smell of fermenting heaps of rubbish, which heap would generate the small-pox contagion, which cholera, which dysentery, and so forth.

The *Report on the Sanitary Conditions of the Labouring Population of Great Britain* in 1842 stated that human excreta should be removed as quickly as possible from its place of deposition and preferably by means of water. The water-closet became almost a fetish of the sanitary mind and the disposal of huge volumes of water-borne sewage and of accumulations of heaps of town refuse became the dominant problems of environmental sanitary science in England. The disposal of town refuse is still an unsolved problem; a recent report on the disposal of London's refuse revealed the fact that the old 'kitchen middens' of the ancients had merely been replaced by hills of rubbish above ground. The problem of sewage treatment was more successfully attacked.

The discovery that septic-tank action would rapidly break down the organic elements of domestic sewage was the first step in progress. It dominated sewage treatment for nearly 30 years, however, and blinded nearly everyone to the fact that real purification lay in oxidation and aerobic action, and not in anaerobic or septic action.

There was, however, an undercurrent of thought that water-borne sewage systems were wasteful, and it is said that Victor Hugo, the poet, walrus-like, 'wept to see such quantities' of nitrogen going seaward in the Seine. Sewage farms became fashionable, but unsuccessful. The chemistry of plant life and the nitrogen cycle were imperfectly understood.

Advances came from two directions. Firstly, the relationship of mineral matter and organic matter to soil fertility was closely studied. Liebig in 1840 led the way to the utilization of 'artificial' manure of mineral composition in the form of nitrate, phosphate and potash. Later investigation showed that this was not the whole story, however, and the part played by the micro-organisms of the soil in crop

production began to be studied and understood. Here, as in many other departments of human activity, experience and empiricism had fore-shadowed scientific investigation and explanation. The Chinese had for ages realized the value of animal excreta for the betterment of crops. They were, moreover, the first to grasp and act upon the master idea that the growth of a crop involves two separate processes, firstly, the preparation of vegetable and animal wastes which must be done outside the field and, secondly, the actual growing of the crop. The Chinese do not put crude night-soil or sewage on the soil; they treat it first in pits. These two definite steps may be scientifically stated as (a) the formation of 'humus' and its incorporation into the soil, and (b) the slow oxidation of this product accompanied by the production of nitrogen in a form available to plant life. Both these processes are the result of fungal and bacterial action. The first is an intense process and should take place outside the soil. If it takes place in the soil, it is bound to interfere with the development of the crop. For this reason the continuous treatment of soil with crude sewage for agricultural purposes is difficult and usually unsuccessful in actual practice.

Other advances came from the side of sewage purification. It was realized that the septic-tank system resulted in a great loss of nitrogen in the form of gas by fermentation. Attempts were made to cut out the anaerobic process by direct oxidation by blowing air through sewage. Nothing seemed to happen, however, and the experiments were abandoned. The perspicuity and persistence of Dr. Gilbert Fowler, however, led to a repetition of this work. He showed that long-continued aeration of sewage led to its ultimate purification by aerobic organisms alone, with a resultant brown 'sludge' in which the aerobic organisms resided. This sludge could be prepared and collected, and used in the requisite quantities for treating raw sewage. Fowler claimed that by this method nitrogen loss was avoided, and that nearly all the original nitrogen was conserved, both in the effluent and in the sludge, in a form readily available for plant life. The sludge therefore corresponds to the 'humus' of the drier method of production. Fowler's contentions have been upheld and the difficulties of taking advantage of his method of sewage treatment for agricultural betterment have been mainly mechanical. The residual sludge is bulky, wet and difficult to handle. These difficulties have been partly, but not completely, overcome. The more modern treatment of sludge by digestion and gas production, however, threaten to oust the agricultural side of Fowler's process. In America and England definite monetary success has been reported from the activated-sludge process. In India the installations have successfully achieved their object of purification, but the agricultural side

has not been very successful. One very important result of the activated-sludge system is its germicidal action. Stewart and Ghoshal, working in the All-India Institute of Hygiene, Calcutta, showed that in the end-result typhoid and cholera germs are definitely destroyed by the activated-sludge process, while there is also a very striking reduction in the numbers of intestinal *Bacillus coli*. This result is a striking contrast to the usual treatment of sewage by septic tanks and trickling filters. The same workers showed that the intestinal flora of the effluent of septic tank and filter treatment is practically identical with that of raw sewage, and typhoid bacilli have on numerous occasions been isolated from such effluents. In the matter of health, therefore, the principle of the activated-sludge process represents a very definite advance.

On the treatment of vegetable waste for agricultural purposes, a tremendous amount of work has been done in Great Britain, in the United States and in India. The treatment of vegetable waste in pits is very old. Modern science has shown the breaking down of lignins and celluloses to be due to the action of fungi and to various aerobic bacteria. Both these classes of organisms demand large amounts of available combined nitrogen and phosphate as food and a favourable reaction (i.e., alkaline). 'Adco' is a patented product devised at Roehamptonstead containing the requisite nitrogen and phosphatic food for the fungi and bacteria, and a lime base for the neutralization of acidity. 'Adco' hastens the formation of humus, or compost as it is called, from vegetable waste by promoting intense fungal and microbial action. In India, excellent and pioneer work at Indore has shown that the urine and dung of cows can adequately, and far more cheaply, replace the 'Adco' mixture. Details of this work are given in Howard and Wad's book, *The Waste Products of Agriculture*, which most of those interested in the matter will have read.

From Fowler, however, we believe came the first suggestion that activated sludge could usefully replace 'Adco' in the preparation of compost, and later that raw night-soil could equally well fulfil the same purpose. Experiments on a small scale by Fowler and others showed that the suggestion was quite feasible. In our present issue we publish the results of two large-scale experiments at Indore and Mysore respectively, where the compost for agricultural purposes is prepared in large amounts from town waste (mainly vegetable) and night-soil. The authors of these papers would probably hold that the work is no longer experimental but a demonstrated fact.

On the agricultural side, the evidence and the authority of the authors are sufficient testimony that this is so. From the economic side also, it would appear certain that if the processes are designed, conducted and supervised on the

lines described by the authors of the papers in this issue, such undertakings should result in a profit.

The subject deserves the closest consideration and attention from administrators, civil, medical and public health. In the ordinary municipality in India we have as a rule the 'removal' or 'conservancy' system of night-soil disposal, and in the majority of villages nothing at all in the way of any organized conservancy. In both cases there is danger to health, and nuisance and waste. In the ordinary Indian towns, the nuisance and danger of conservancy exist chiefly at three points, viz., in the privies (both public and private), in the removal of crude night-soil through the streets and lanes by buckets or carts, and at the trenching ground. The last named is a source of nuisance and danger by breeding flies, and is usually un-, or but slightly, remunerative. The utilization of night-soil for compost would remove these drawbacks. We are assured by the authors that pathogenic bacilli would be destroyed in the fermentation process. This is probable but specific work similar to that done on the activated-sludge process seems necessary. The privies and the street cartage would still remain, however, and these are by no means the least of the disadvantages and dangers of the ordinary conservancy system. Then there is the question of supervision. The process is based on fairly well-defined scientific principles which the supervisors should understand and see

carried out. We agree that it should not be impossible to train a sanitary staff to carry out the process with understanding, but the state of a compost factory utilizing town refuse and night-soil run badly or carelessly can be readily imagined. There is also the question of salability of the compost product. At Mysore there seems to have been no difficulty in disposing the compost at a profit, but we have no assurance that this will continue indefinitely. There is still a prejudice in the mind of the Indian cultivator against handling products made from human night-soil. Mr. Brayne in the Punjab managed to achieve a certain success with his village refuse pits, but a great part of the result was, we believe, due to his personal influence and not to the conviction of the villagers in the efficacy or benefit of the measure, nor to their willingness or desire to try new and economical methods. We think the authors of the two papers in our present issue have proved the feasibility and the advantages of their methods and we hope that the subject will receive the closest attention of agriculturists and sanitarians throughout India. Further trial and experiment are probably necessary under the varying conditions of Indian village and town life, but we feel convinced that, could the methods described be put into practice, they would add much to the health and prosperity of millions of our Indian people.

ORGANIC MANURE FROM STREET REFUSE AND NIGHT-SOIL AT MYSORE CITY, INDIA*

By J. J. MIELDAZIS

Sanitary Engineer

THE development of efficient methods of refuse and garbage disposal have not kept pace with the perfection of sewage disposal processes now commonly adopted throughout the world. The most common methods of refuse and garbage disposal are dumping on land or at sea, feeding to hogs, incineration, and reduction. Other methods include the pulverizing of refuse by machinery prior to sale as fertilizer (Soper, 1931) and the Beccari system of fermenting mixed refuse into a form suitable for sale as fertilizer (Hyde, 1932). But, with few exceptions, none of these methods produce revenue returns commensurate with the amounts invested

for disposal plants. It may safely be said that the disposal of street refuse is a costly obligation to any community.

In an agricultural country like India, the manurial value of a mixture of street rubbish and night-soil is recognized to such an extent that agriculturists make periodic trips to the cities for the collection of these ingredients. In some cases, municipalities are able to get revenue returns by contracting the collection of refuse of certain portions of the city to agriculturists in need of the fertilizer. In India garbage is almost unknown. The street refuse collected consists mainly of straw, paper, coconut husks, bits of clothing, cardboard, leaves, weeds, stones, broken pottery, tins, glass, and fine dust, together with an appreciable amount of night-soil which finds its way to the rubbish bins. The agriculturist loads his cart with alternate layers of this heterogeneous mass of refuse and night-soil and carts the mixture to his fields, where it is formed into piles and allowed to decompose for a period of four to six months. When it is sufficiently broken down into an odourless humus mass, it is used as

* The experiments and observations referred to herein were conducted with the support and under the auspices of the International Health Division of the Rockefeller Foundation and the Government of Mysore, India.

fertilizer on his fields. This process dates back forty centuries to the early methods of composting in China (King, 1911). Japanese agriculturists have been taught how to conserve the fertilizing value of night-soil for use in their fields (Smith, 1908). Dr. Gilhert J. Fowler (1930), after considerable experimenting in India, was able to compost street rubbish with cow-dung and night-soil solutions at Nasik, Cawnpore, and Bangalore. Howard and Wad (1931) developed the Indore method of composting at the Institute of Plant Industries at Indore.

After a study of these experiments and consultation with Dr. Fowler, the composting of street rubbish with night-soil was carried out at Mysore city. Mysore city, the capital of Mysore State, India, with a population of 107,042 and covering ten square miles, lies at an elevation of 2,500 feet and is situated about three hundred miles west of Madras city in south India. The average annual rainfall is 29.75 inches. It starts with early showers in April and May which lead to the south-west monsoon rains during June, July, and August. A few showers occur during the north-east monsoon of October and November.

The conservancy of street rubbish and night-soil in Mysore city prior to July 1931 was typical of most Indian cities of its size. The Mysore City Municipal Regulations prescribe that :—

'Dust, dirt, dung, ashes, garden, kitchen, or stable refuse or filth of any kind or any animal matter or any broken glass or earthenware or other rubbish, or any other thing that may be a nuisance shall not be deposited in any street, drain, or open space except at such places in such manner and at such hours as shall be fixed by the Municipal Council.'

In order to facilitate the collection of street rubbish and refuse mentioned above, the municipal council provided a number of dust bins in which such refuse was to be deposited by the householders.

The transportation of the collected refuse to the municipal dumping grounds presented quite a problem to the municipality. The bullock carts used for collecting the rubbish were unsightly and were continuously breaking down, leaving the load of street rubbish, with its inevitable deposits of night-soil, along the city streets until repairs could be undertaken or an empty cart obtained to remove the load. The sides of these carts were composed of woven bamboo, generally patched with old gunny sacks. Owing to the speed of the bullock and the distance to the dumping ground on the outskirts of the city, it was necessary to establish temporary dumping stations within the city to which the bullock carts transported their loads. Motor lorries of the city picked up the rubbish from the temporary dumping grounds and made the long trip to the main dumping ground.

The conditions around these temporary dumping grounds may well be imagined. There was no impervious floor and there was always some refuse left on the ground. They presented ideal places for the collection and breeding of flies.

The latrines in this city present a variety ranging from the popular open-pit type, or a conservable latrine in various stages of disrepair, to a flush latrine connected with the city underground system. Despite Mysore city's 67 miles of underground sewage line, the number of flush latrines within the city prior to June 1931 was less than a hundred. The usual type of conservable latrine consists of a squatting slab with a hole, underneath which is a basket about 18 inches in diameter and about 6 inches deep. The basket is provided with a lining of palas-kino leaves sewed together to form a mat about a foot in diameter. These leaves are used by the high-caste Brahmins instead of plates, and after meals they are discarded into the rubbish bins where they are collected by the scavengers. The scavenger empties the night-soil with the leaf lining and covering of ashes or dirt into the night-soil cart and replaces the basket with a new leaf lining.

The transportation of night-soil was even more precarious than the transportation of street rubbish. This important phase of sanitation was executed by a number of agriculturists partially subsidized by the municipality for carting away the night-soil collected by private scavengers and municipal sweepers from pit latrines, conservable latrines, and open spaces within the city. These agriculturists were paid Rs. 5 per month for a double bullock cart and it is quite obvious that their visits to the city were prompted more by the value of the manure collected than the compensation received from the municipality. As a result, the conservancy in the city had to suffer when their agricultural duties kept the collectors in their fields. It was impossible to enforce regular attendance and as a result some sections of the city were not conserved for days on end. The householder who employed a private scavenger was more fortunate; he had his conservancy carried out even though the contents of the latrine finally reached one of the municipal rubbish bins.

In June 1931, the municipal council, with the aid of substantial government loans and a two per cent sanitary cess, undertook the conservancy of street rubbish and night-soil. New rubbish and night-soil carts of approved design were built to replace the rickety carts in use. The municipality was then confronted with the problem of the proper disposal of the night-soil conserved from the city.

Experimental work in composting had been begun at Mysore city in January 1931. Street rubbish collected from the city was formed into small heaps and treated with an emulsion made up of one part night-soil and four parts water.

The rubbish was completely decomposed in six weeks and on analysis was found to contain:—

Moisture	..	12.73	per cent
Organic matter	..	17.06	" "
Phosphoric acid	..	0.87	" "
Potash	..	1.26	" "
Nitrogen	..	0.81	" "

The Department of Agriculture became interested in the results obtained and was soon convinced that compost was an ideal organic manure for the cultivation of sugar-cane. The completion of the Krishnarajasagara Dam and the Irwin Canal had just brought 125,000 acres of land under irrigation within 30 miles of Mysore city. Since sugar-cane cultivation was being encouraged in this area, the municipal council saw the prospects of an unlimited demand for their product and decided upon composting as the most economical method of disposal of their two most important nuisance problems, *viz.* night-soil and street-rubbish disposal.

Method of composting

At Mysore city, about 1,800 gallons (18,000 lbs.) of night-soil are collected each day. Taking the average daily amount of human excreta as 5 ounces, this represents a collection from 45,000 people, that is about 50 per cent of the total city population. Most of the remainder of the excreta is collected from the streets and open spaces in the city and dumped into the refuse bins. This mixture is what makes the street refuse of Indian cities so valuable as manure.

The street rubbish is brought to the sewage farm by carts and lorries and dumped alongside a line marking the site of a new pile. This rubbish is then forked into place to form a pile 6 feet wide at the base, 4 feet at the top, 2 feet high and about 500 feet long. Large stones, glass, and bits of earthenware pots are removed by hand at this stage. The night-soil collected by the municipal staff each day is brought to the sewage farm in night-soil carts drawn by one bullock and in charge of one driver. These carts are so constructed that they can be tilted at the rear and the contents dumped. The night-soil as received is a fairly dry mixture of night-soil, leaf linings of night-soil baskets, ashes, and dirt, filling about one-third of the cart. To this mass sufficient water is added to make a mixture of one part of night-soil and two parts of water. The contents of the cart are then stirred and applied to the piles.

The piles of rubbish to be treated each day are first trenched by four coolies before the arrival of the night-soil carts. The trenching consists of pulling the centre of the pile toward the edges so as to form a V-shaped trench about a foot deep in the centre of the pile. The contents of the night-soil carts are then dumped into these trenches. Each cart is tilted four

times at intervals of about 12 feet and the emulsion spread uniformly in the trench. As soon as one rubbish pile is treated, the sides of the pile are pulled back to the centre completely covering the deposit of night-soil emulsion. A

Fig. 1.—A view of the composted field.

Fig. 2.—Applying emulsion to trench in rubbish heap.

Fig. 3.—Close-up view of emulsion in trench showing the presence of leaves brought in with the night-soil.

sufficient number of rubbish piles are formed so that each pile receives night-soil treatment every seventh day. The piles undergoing decomposition are turned each week by forking the contents of the pile into an entirely new position. During dry weather it is necessary to water the piles in order to bring the moisture content to a damp state without being wet. This is done by applying water to the tops of

the piles from an ordinary sprinkling cart two days before the application of the night-soil.

The method described above resembles the ordinary trenching of night-soil except that it is done under aerobic conditions. Fermentation is set up with the development of moulds and bacteria and high temperatures are produced in the pile. The raw rubbish gradually attains a brownish colour and after six to eight weeks is completely broken down into a smooth brown humus containing particles of the more resistant bits of rubbish which withstand the fermentation process. The finished product is screened through expanded metal screens of one-half inch mesh. The fine material is stored in heaps for sale and the coarse screenings, with the stones, bits of earthenware, etc., removed, are added to rubbish heaps undergoing decomposition. Dr. Fowler recommends that only half the finished heap be removed for storage and that the remaining portion be mixed with fresh rubbish, in which it acts as an activator and hastens the process. This recommendation is now being carried out at Mysore city and a considerable saving in the time required for the process is noticed. The mixing of the raw and digested material is similar to the 'seeding' process in common use in sewage-disposal plants and Beccari cells.

moisture content of less than 65 per cent. If the pile is allowed to become sodden, the temperature is reduced and the growth of the moulds is impeded.

Experiments

It was necessary to carry out certain experiments in order to lay down specific instructions which could be followed by those interested in the process. The author enlisted the aid of Dr. Leslie C. Coleman, M.A., Ph.D., C.I.E., Director of Agriculture in Mysore State, and of Dr. Gilbert J. Fowler, D.Sc., F.R.C., Representative in India and the Far East of Activated Sludge Ltd., Bangalore, South India, in defining certain experiments necessary for the establishment of the process. It was finally agreed that the success of composting depended upon the solution of the following problems:—

1. The proper interval of application of night-soil emulsion
2. The strength of night-soil emulsion to be used
3. The rate of application of night-soil emulsion
4. The period of turning

With these requirements in view, experiments* were outlined to be carried out at the Mysore

Fig 4.—Storage heaps of finished compost. Experimental piles in left foreground.

It may be said that the process becomes odourless shortly after the night-soil emulsion in the trenches is covered with rubbish. The temperature in the piles begins to rise on the second or third day after the application of the night-soil mixture. Within a week temperatures of 48° to 50°C. have been recorded (air temperature 27° to 28°C.). It was impossible however to maintain uniformly high temperatures throughout the pile because of the heterogeneous nature of the night-soil emulsion and the difficulty of getting this thoroughly mixed with the street rubbish. Moulds begin to form after the first week and continue to spread throughout the pile wherever the temperature and moisture conditions are favourable. Their growth is more rapid in those sections of the pile that have a

sewage farm under the supervision of an agricultural inspector.

Fly breeding

Some fly breeding was experienced in the compost work as carried out on a large scale at Mysore city. The presence of leaves and other foreign matter in the night-soil made it impossible to prepare a uniform night-soil emulsion for application to the piles with further treatment. It was therefore difficult to maintain the uniformly high temperatures inimicable to fly

* In the interest of economy of space we have been compelled to omit details of these and the fly-breeding experiments referred to below. The practical outcome of the experiments were, however, the formulation of 'Instructions for composting' which are given below in full.

breeding. It was found that the number of flies present was due to the following three causes:—

- (a) Adult flies harbouring on the night-soil and rubbish carts returning from the city
- (b) Fly larvæ and maggots included in the night-soil and rubbish collected from the city
- (c) Fly breeding in the compost heaps

The first source is not of importance, since it is a means of diminishing the number of flies in the city. The last two sources, however, had to be controlled, if this method of composting was to become popularized. It was noticed that fly larvæ and maggots in the compost piles were most numerous between the leaves brought in with the night-soil where accumulations of raw night-soil resulted in a decrease in temperature. Fly larvæ in different stages of development were found in compost piles recently treated with night-soil. The piles treated with night-soil prior to the fourth day before the investigations and showing decomposition of the night-soil contained only a few large larvæ.

During the experimental work in composting, there was no fly breeding in the piles. The emulsion used was a properly-mixed uniform emulsion of night-soil and water with all extraneous matter, such as leaves, removed. This was in accordance with the experiences of Fowler and Howard and Wad, who reported an absence of fly breeding during composting. The secret of fly breeding in the piles depends upon the condition of the emulsion when applied. This was demonstrated by the treatment of experimental piles on a fly-trap platform.

In this experiment the number of larvæ rose from 72 on the second day to 3,849 on the third day and to 7,648 on the fourth day. The peaks in this curve rose abruptly about the time that the night-soil solution was added and except for the fourth week the peaks are gradually reduced until the seventh week, when a maximum of 29 larvæ were collected on any one day.

It must be borne in mind that with each application of the night-soil emulsion countless numbers of fly larvæ were introduced into the pile. Most of these were killed off by the high temperatures maintained. As the process approached the completed stage, the condition of the refuse was more homogeneous and higher temperatures were more easily maintained.

Fly larvæ introduced into the experimental piles with the night-soil emulsion were destroyed by the uniformly high temperatures maintained; no larvæ were noticed either on the platform or in the surrounding trenches.

Instructions for composting

The experiments carried out and the experience gained with the original experimental heaps show that street refuse can be composted into a valuable organic manure without fly breeding when a properly emulsified night-soil solution is prepared. The results of the experiments for the establishment of a process for composting

indicate that the following procedure should be followed:

1. Place the rubbish in piles 6 feet wide at the base, 2 feet high and 4 feet wide at the top. Separate all glass, tins, earthenware pots, stones, etc.
2. Trench the pile down the centre for the application of the night-soil emulsion.
3. Prepare a uniform emulsion of one part night-soil to four parts liquid, carefully excluding all leaves and other extraneous matter.
4. Apply the emulsion to the trenched rubbish piles at the rate of two gallons per running foot. Close the trench in the pile.
5. Apply the emulsion to the rubbish piles daily for a period of about two weeks or until the pile becomes fairly moist. Then make applications to the pile every third day. The interval of application will depend upon the weather conditions. When rains are fairly heavy, the strength of the emulsion may be increased and the rate of application decreased. If the rains are continuous and heavy enough to soak the piles thoroughly, some shelter must be provided in order to maintain the high temperatures necessary for composting.
6. When the rubbish has broken down into a brown humus mass one-half of the pile may be removed and stored for screening; the remaining portion of the pile may then be mixed with raw rubbish and the process repeated as from the beginning.

In communities where the night-soil is collected free of extraneous matter, composting may safely be carried out by the above method without fly breeding. In order to ensure a uniform emulsion, the night-soil may be mixed with the proper proportion of water and allowed to liquefy before application to the piles. This liquefaction will reduce the solid lumps of night-soil which would require additional time to break down in the rubbish pile. In Mysore city, the process is being improved by the construction of a macerating tank (see figure 5) in which the leaves are removed from the night-soil in preparing the emulsion and the solid lumps are allowed to liquefy. The contents of the night-soil carts are dumped into the smaller portion of the tank into which the proper amount of water is added and the mass is thoroughly agitated with forks and compressed air until the leaves are removable. These leaves are removed from the tank and mixed with fresh rubbish heaps. The emulsion passes over a weir protected with an expanded metal screen into the larger chamber from which it is drawn off for application to the piles. At present, the night-soil carts, after dumping, are

refilled with the emulsion for application to the piles. There is a proposal to lay pipe lines to convey the emulsion to the rubbish heaps so that the applications may be made by means of

Fig. 5.—View of night-soil cart showing the condition of night-soil as received at macerating tank.

a rubber hose. This would be less offensive and would ensure a more uniform application.

The author has composted all house refuse and garbage excepting tins and glassware, including leaves and weeds collected from his garden, for a period of two years. A small septic tank was constructed for the treatment of night-soil conserved from the bungalow. The effluent from the septic tank, *plus* daily withdrawals of sludge from the bottom of the tank, were mixed in equal proportions and applied to the refuse heap at the rate of two gallons per cubic foot. This process was carried out successfully without fly breeding and was free from odour. The amount of compost produced was sufficient for the fertilization of the flower beds in the compound.

COST OF COMPOSTING

In a discussion of costs, it is difficult to separate those items which should definitely be charged against the collection and those which should be charged against the compost making. For example, the drivers of the night-soil and rubbish carts are responsible for the ultimate disposal of their cart loads. They therefore receive no extra remuneration for dumping the rubbish or for preparing and applying the night-soil emulsion to the rubbish heaps.

Before going into the cost of composting, it would be advisable to determine the unit costs of collection and disposal of night-soil and rubbish.

The cost of night-soil collection is as follows:—

	Rs.
16 sanitary inspectors at Rs. 70 plus 10 per mensem ..	15,360
55 conservancy peons at Rs. 12 per mensem ..	7,920
110 scavengers at Rs. 11 per mensem ..	14,520
55 night-soil carts, operation and maintenance at Rs. 22-8 per mensem ..	14,850
TOTAL Rs. ..	52,650

As the above cost represents the collection from about 45,000 people, the annual cost of night-soil collections is about Re. 1-3-0 *per capita*.

If this night-soil were to be trenched, the cost of such trenching is estimated as follows:—

1 sanitary overseer at Rs. 50 per mensem	Rs. 600
10 coolies at Rs. 12 per mensem ..	1,440
TOTAL Rs. ..	2,040

The cost of rubbish collection is as follows:—

5 sanitary inspectors at Rs. 80 per mensem ..	Rs. 4,800
15 sanitary overseers at Rs. 50 per mensem ..	9,000
49 peons at Rs. 12 per mensem ..	7,056
440 sweepers at Rs. 11 per mensem ..	58,080
50 rubbish carts, operation and maintenance at Rs. 22-8 per mensem ..	13,500
2 lorries—operation and maintenance ..	6,800
Repairs to dust bins ..	1,400
TOTAL Rs. ..	1,00,636

The average annual collection of street rubbish amounts to about 20,000 tons or about Rs. 5 per ton.

The staff employed in the dumping of street rubbish is as follows:—

1 sanitary overseer at Rs. 50 ..	Rs. 600
12 coolies at Rs. 12 ..	1,728
TOTAL Rs. ..	2,328

The labour and supervision charges which might be said to represent the costs incurred in the making of compost are as follows:—

	Total per annum
1 supervisor at Rs. 80 per mensem ..	Rs. 960
1 maistry at Rs. 12 per mensem ..	144
Coolies for	
Preparing heaps 4	} 20 coolies at Rs. 10 per mensem .. 2,400
Trenching .. 2	
Assisting night-soil cart drivers 2	
Turning .. 4	
Watering .. 2	
Screening .. 4	
Clearing .. 2	
20	

Contingencies	146
TOTAL Rs. ..	3,650

On the basis of 4,000 tons per year, the cost of composting amounts to less than Re. 1 (\$0.30 gold) per ton.

Summary

Ordinary street refuse, consisting of paper, rags, cardboard, straw, leaves, weeds, etc., can be composted into a valuable organic manure by treatment with night-soil emulsion.

The process may be carried out without fly breeding, provided a uniform emulsion of night-soil and water, free of leaves and solids, is used.

One thousand gallons of night-soil per day, properly emulsified in the proportion of one part night-soil to four parts water, will produce 4,000 tons of compost per year from about 45,000 tons of street rubbish.

THE SANITARY DISPOSAL AND AGRICULTURAL UTILIZATION OF HABITATION WASTES BY THE INDORE PROCESS

By F. K. JACKSON

and

Y. D. WAD

Institute of Plant Industry, Indore, Central India

Sanitation—the present position

THE sanitary disposal of refuse and human waste, so essential to the welfare of humanity throughout the world, is still far from being universal, or even widely practised. This is partly due to the apathy of the general public who have a natural aversion to such a subject, and in many countries it is dealt with in a casual way even by public authorities who are also often handicapped financially. These facts restrict the use of methods of disposal involving skilled attention and costly operation or outlay*. Even where such methods are used their practical efficiency is sometimes far from that desirable and attainable.

Even the more progressive parts of the world still use comparatively cheap and simple methods while in India and similar countries the problem is further complicated by the habits and extreme poverty of the people. At the

*For instance, in the activated-sludge system, the most up-to-date method, with 15 gallons sewage per head, the capital cost is Rs. 500 per 1,000 population, and the annual operation cost annas 14 per head (Williams, 1924).

(Continued from previous page)

The cost of composting amounts to less than Re. 1 per ton and in Mysore city yields a profit of over 275 per cent on the annual operation charges.

The cost of composting and the area required can be reduced considerably by the installation of a piped system for the application of the night-soil emulsion.

Street refuse and kitchen wastes may be composted by treatments with sewage sludge in place of night-soil emulsion.

This work has been the result of the co-operative efforts and valuable suggestions of Dr. Gilbert J. Fowler, D.Sc., F.I.C., Representative in India and the Far East of Activated Sludge Ltd., Bangalore, Dr. Leslie C. Coleman, M.A., Ph.D., C.I.E., Director of Agriculture in Mysore State, and Mr. T. G. Rama Iyer, B.A., President, Municipal Council, Mysore City.

present time in India both night-soil and refuse are disposed of in the following ways:—

(1) In rural areas they are promiscuously scattered near habitations and along pathways and watercourses, thus endangering health.

(2) In urban areas the refuse is either tipped on outlying land and left to rot, or is used to fill up depressions; a portion is sometimes sold as fuel to potters. In a few places it is dumped into large rivers or the sea. The night-soil is collected and carted, in an advanced septic condition, either direct to cultivated land, or to trenches of various sizes and depths where it is covered with earth, or with earth mixed with ashes and refuse. Sometimes, after a year or more, crops are grown on the site of the trenches, or with the rotted manure taken from them. In practice the trenching method produces noxious odours, often allows flies to breed, and can hardly be called a sanitary means of disposal.

(3) Even in the few cities served by a water-borne sewage system, the sludge is always difficult to handle, and other refuse has still to be dealt with usually by incineration (Williams, 1924), (Leather, 1895), (Kelkar, 1909).

In Western countries also, collection and carting of night-soil is still generally practised in the smaller communities and in outlying parts of cities. The refuse is handled in much the same way as in India, though sometimes a little sorting is done to obtain by-products, or differential treatment given to special kinds of waste, but this only applies to well-organized cities (Hering and Greely, 1921).

The agricultural aspect

From the agricultural point of view the position is still less satisfactory. As early as 1893 Dr. Voelcker regarded 'the spread of a good system of utilizing human and household refuse, street sweepings, etc., on the land as a most potent factor in the improvement of Indian agriculture'. Dr. Leather again emphasized the point in 1895, thus:

'There is, perhaps, no more important subject in relation to agriculture than the proper disposal of night-soil and other town refuse, for it may be said, without exaggeration, that nearly one-half the plant food extracted by food-crops from soil is contained in the materials which are included under these two heads. It follows, therefore, that on their proper disposal and return to the soil, depends the addition of a large proportion of the food necessary for the crops'.

This pronouncement is beyond denial. The enormous potential manurial value of habitation wastes—very little exploited in any part of the world for want of suitable means—is displayed in the following figures (table I).

The high crop-production value of human waste is known and for centuries advantage has been taken of it by the Chinese (King, 1926); yet in other tracts, including India, it has never been sufficiently made use of owing to prejudice rather than to ignorance (Kelkar, 1909). Applied in any form high yields of a great variety of crops are obtained.

TABLE I*

	PERCENTAGE COMPOSITION			AMOUNT OF WASTE AND MANURIAL CONSTITUENTS, IN IT PER CAPITA ANNUALLY, IN POUNDS			
	Town refuse	Human faeces	Human urine	Town refuse	Human faeces	Human urine	Total
Organic matter ..	22.62	21.72	4.85	122.7	23.2	46.9	192.8
Nitrogen ..	0.7	1.57	1.00	3.80	1.68	9.67	15.15
Potash K ₂ O ..	0.27	0.55	0.18	1.46	0.59	1.72	3.77
Phosphorus P ₂ O ₅ ..	0.43	1.23	0.15	2.33	1.32	1.45	5.10
Amount of waste	543.00	107.0	967.0	..

* Table I is compiled with the aid of data given by Brittain, Hering and Greely.

Compared with artificial manures organic manures appear to be of specific importance in other directions, namely, their influence on the reproductive capacity of the seed produced and on its feeding value to animals and man. Vishwanath and Surya Narayana (1927) found that seed from a crop of *ragi* (*Eleusine coracana*), which had been grown with farmyard manure, gave higher yields than crops sown with seed raised with artificial manures or without manure. McCarrison (1926) has shown that grain produced on farmyard manure contains more vitamins than that grown with mineral manures. Ramiah (1933) reports that forage crops (*ragi* straw) grown on farmyard manure are similarly rich in vitamins.

In the light of the foregoing summary few sanitarians and no agriculturists would quarrel with the statement that the ideal disposal of habitation wastes is to send them back to the land as organic manure. It may be argued that this has been done already in the majority of disposal systems, but it has generally meant enormous waste of organic matter and of nitrogen because of the long-continued anaerobic fermentation that occurs after burying and also in water-borne sewage. Further, the area of land to which the wastes are actually returned by these systems is a minute proportion of the area which feeds the population producing the wastes, and that minute proportion is excessively dosed. In addition the return of wastes to the land under these systems seldom even meets the cost of disposal.

Sanitation methods conserving manure

It is true that for centuries the Chinese have been returning their habitation wastes to the land in agriculturally suitable doses but they have paid little regard to sanitation. On the other hand all the modern biological systems of disposal, from the septic tank to the aerobic filters, deal mainly with the sanitary aspects, the agricultural side being treated as of minor importance. Methods of the type of the activated-sludge system of Dr. Fowler are perhaps the first attempt to aim at full conservation of plant food in addition to satisfactory sanitation. These developments apply only to night-soil. Other refuse is still allowed to rot as it may,

or its organic matter is completely lost by burning. Kelkar (1909) mentions, among other current methods* for disposal, the drying of night-soil with ash by frequent stirring; also trenching in a pit in alternate layers of refuse and night-soil covered with earth. An apparently similar method has now been announced by Viswanadha Ayyar but chemicals are used to deodorize. Details of technique, costs and quantities are not given. The idea of treating both night-soil and refuse together, with the intention of securing optimum aerobic biological activity, is of recent date.

During the attempts to solve the difficulties of utilizing activated sludge, Fowler (1903) made compost with agricultural wastes, using sludge as a starter. He also suggested the use of night-soil for composting refuse on the basis of the fundamental principle [discovered by Russell and Richards (1917) and further developed by Hutchinson and Richards (1921)] of converting straw to humus with nitrogen by means of aerobic fermentation. Fowler's experiments have recently resulted in a formulated process described by Anstead (1932). The factors involved in the decomposition have been studied further by Rao and Subrahmanyam (1932). Howard and Wad (1931) indicated the possible adaptation of the Indore method of composting farm wastes to the utilization of habitation wastes.

Essentials for disposal of habitation wastes

The essentials of any system likely to be adopted universally appear to be:—

- (1) Immediate treatment of all habitation wastes as they arrive at the disposal ground
- (2) No proportioning of refuse to night-soil or other pre-treatments, such as liquefaction
- (3) No fly breeding or noxious odours
- (4) A simple routine technique with as few operations as possible
- (5) No need of skilled supervision. The sweeper class ought to be able to manage the working by themselves.
- (6) A simple installation with small capital outlay and low operation costs

The ideal set by these essentials does not seem to have been attained by any process in vogue.

Conservation of nitrogen

It must be emphasized that complete conservation of all nitrogen supplied by human waste is only possible if sufficient quantities of refuse are available carrying enough non-nitrogenous organic material to balance the total amount of nitrogen. In actual practice this seldom or never happens. The average organic matter in mixed refuse, faeces and urine, per head of population per year is about 192.8 lbs.,* while the nitrogen contained in it amounts to about 15.5 lbs., giving a ratio of 12.7 to 1. One hundred and forty-three parts of organic matter of the nature of straw will utilize, for complete decomposition, only 1 part of nitrogen, any excess being lost. Thus habitation wastes contain far more nitrogen than can be conserved in practice. Any attempt at greater conservation (without sufficient non-nitrogenous organic refuse) necessarily involves an unstable putrescible product, hence such disposal is not sanitary. Actually, even a lower proportion of nitrogen seems to be effective, because, in a properly conducted decomposition, fixation accurately adjusts any deficiency.

The maintenance of high nitrogen content in soils need not be allowed to become a fetish if sufficient humus is supplied. There is always a limit to the amount of nitrogen that soils can hold, depending on the type and the climate (Jenny, 1928). Perhaps 'it is more economic to maintain a low nitrogen level in the soil and to keep the nitrogen active by maintaining a narrow N : C ratio rather than to try to build up a high nitrogen content' (Lyon, 1929).

Hence it is more reasonable to direct special attention to quick and sanitary disposal of whatever proportions of refuse and night-soil are available rather than to lay stress on full nitrogen conservation. Natural fixation of nitrogen in soil from the air is generally not sufficiently taken into account when assessing nitrogen removed by crops. It is the balance between addition by fixation and the removal by crops that matters. Phosphorus and other components of habitation wastes can, however, be wholly recovered.

The Indore process

(a) *Development.*—While the Indore process for composting agricultural wastes was undergoing adaptation to a few special local conditions the Member in Charge, Medical Department, Holkar State [Lieut.-Col. J. R. J. Tyrrell, C.I.E., I.M.S. (retd.)], invited the Institute of Plant Industry to extend these adaptations to the treatment of habitation wastes and offered facilities for trials at the disposal grounds of the Indore Municipality. These trials, which had been contemplated by Howard and Wad (1931), began in March 1932 and were duplicated almost simultaneously in the Residency area at the suggestion of the then Chief Medical

Officer in Central India. The trials were entirely successful from the first and a simple technique was rapidly developed. Within a few weeks, at the Residency area disposal ground, all incoming wastes were being composted by the new method and it was soon decided to follow suit at the municipality's main disposal ground (serving a population of 60,000) as soon as the necessary trenches and roads could be made. This has since been done and the new process is in full operation. Neemuch (C. I.) cantonment and the Malwa Bhil Corps at Indore also have abandoned their old systems in favour of the Indore process.

(b) *The main features of the Indore process are—*

(1) The immediate treatment of both the refuse and night-soil, one after the other, as soon as they arrive at the disposal grounds, the carts being backed to the edge of a trench 2 feet deep and 15 feet broad.

(2) The addition of half-rotted compost in small amounts as a starter.

(3) Lightly spreading by suitable long handled rakes in thin layers so that they become mixed (figure 2).

(4) A rapid rise of temperature (usually to above 50°C. and never below 45°C.) which persists up to the third turn and kills pathogenes and fly larvæ.

(5) The restoration of air three times by turning with a digging fork (figures 3, 4 and 5) to ensure steady and intense microbial activity and to kill (by burying in the hot mass) any maggots that may hatch out at the exposed cool edges of the heaps. The periods between turning are short enough to prevent any such larvæ developing into flies and to reduce the chances of their crawling out in wet weather to shelter and pupate in the bottom and sides of the trench.

(6) The replenishment of lost moisture by adding water, if needed, at the times of turning.

(c) *The advantages* have been found to be :—

(1) Low capital outlay and operating costs.

(2) A net profit from the sale of manure.

(3) Simple construction of permanent trenches not requiring professional engineering knowledge.

(4) Economy in disposal ground area.

(5) The prevention of offensive odours and fly breeding.

(6) The process can be worked in the open without cover in all seasons, even during continuously wet seasons with 47 and 52 inches of rain and heavy falls of nearly six inches in 24 hours.

(7) No need of skilled supervision.

(8) Exceptional cleanliness at the disposal grounds.

(9) The short period required for complete decomposition to a rich manure in large quan-

* See table I.

tities which is safer for crops than ordinary poudrette.

(10) The surplus income becomes available for other sanitary measures for improving public health.

(11) It is equally applicable to large or small communities as shown in table V.

The working of the process is described in detail in the appendix. For nearly two years it has always given satisfactory results, it appears to meet all the essentials of a sanitary disposal system and it is also commercially profitable.

(d) *The course of decomposition* involved in the process is now to be described. On arrival both the night-soil and some components of the refuse are already in a more or less advanced septic condition. Night-soil tends to liquefy as soon as it is allowed to accumulate, with the production of foul, volatile products which have to be destroyed immediately they are produced. The physical nature of fresh night-soil is such that if an attempt is made to mix it intimately with refuse, it fills the interspaces and forms a dense, viscous, anaerobic mass, thus preventing oxidation of the noxious products which continue to be formed at an intensified rate. The wheel turns the other way when, as in this process, the night-soil is only lightly and rapidly spread along with the refuse in fairly thin layers. It then forms a coating on the refuse with wide interspaces for aeration. The partial dessication that follows clots the colloids and slows down their decomposition. The formation of obnoxious anaerobic substances is checked so that the copious aeration is able to oxidize them completely. This is why nuisance is effectively suppressed.

If, however, the trenches are carelessly charged, septic conditions will persist and be intensified. If this happens it will be corrected when aeration is restored at the first turn, four or five days after charging. The danger of nuisance persists until the putrescible nature of the material has vanished and it is no longer a suitable habitat for harmful organisms, even when infected by them. Thereafter there is no danger left. In order to reach this stage quickly the heaps are further mixed, aerated and moistened at suitable intervals to quicken fermentation and keep up the heat until an innocuous product is obtained. Incidentally any maggots in the cooler fringes are turned into the hot mass and killed.

Inoculation of the mass with half-rotted compost while charging is included in the process but the efficacy of this step depends entirely upon aeration, without which no inoculum, however active, will accelerate the initial speed of decomposition. Even with aeration, so little difference has been observed to follow inoculation that its efficacy may possibly be best described as a selective accumulation of a virile biological population. In fact decomposition is

perfectly satisfactory without inoculation, as necessarily happens when starting the process in a new place. It is hence essential to avoid too much liquid in the heap, especially in the beginning. If sullage water in large quantities has to be disposed of simultaneously with night-soil and refuse, this point becomes very important. Such sullage water might perhaps be better disposed of by adding at the second turn. Rain does not offer any difficulty, as with properly made heaps it does not penetrate very deeply and the drainage space left in the trench prevents accumulation.

Rapid crumbling of fibrous material occurs and under favourable conditions may be completed in three weeks, though, as a rule, a slightly longer period is needed, according to the season.

(e) *The economics*.—By adopting this system the financial loss that hitherto occurred in disposal ground management has now been converted into a profit, even when the manure is sold at as low a price as eight annas a cart-load.

TABLE II

ANNUAL EXPENSES AND RECEIPTS OF INDORE CITY DISPOSAL FUND UNDER THE OLD AND NEW SYSTEMS

	Old	New
Expenses ..	Rs. 6,064	Rs. 3,120
Receipts ..	" 1,528	" 6,205
Deficit ..	" 4,535	" ..
Profit	Rs. 3,085

Thus, at the Indore Municipality's disposal ground, under the old system only 25 per cent of the working expenses were met by receipts. Under the new process the receipts are twice the cost of working.

(f) *Intake, output and time*.—The yield of compost is shown in table III.

TABLE III

YIELD OF COMPOST AT INDORE CITY DISPOSAL GROUND

	Cubic feet	Tons
Town refuse ..	52,465	602
Compost ..	30,835	909 *
Refuse per 100 cubic feet compost.	170	..
Refuse per ton of compost.	..	0.66

* Note.—Including moisture, 40 per cent, and solids from night-soil.

Experience has shown that whatever may be the scale of operation the process never requires more than three weeks to reach the third turn. Owing partly to the rapid fermentation the water requirement is low (still lower than for agricultural compost by the Indore process) and even in the hot weather the necessary supply is not a costly item. The production of manure is high—nearly half the original volume of refuse. The average weight of refuse at Indore

was found to be 25.7 pounds per cubic foot and that of ripe manure (moisture 40.9 per cent) 66 pounds per cubic foot. The Indore refuse contained all the usual components, e.g., in an examination of seven tons of refuse from carts taken at random, household wastes, paper, market wastes, fodder residues, animal excreta, potsherds and scrap metal were found.

The cost of making the compost at the Indore city disposal ground has been 3.9 annas per ton (average from daily records taken for over a year). Costs of collection and carting are, of course, excluded, being common to all disposal processes.

(g) *Labour requirements.*—The labour required is unskilled and the cost is low.

by Kelkar to persist in the soil for 10 years. The composition of the ripe compost from various sources has been estimated at intervals; this nitrogen and phosphate compost compares favourably with manures from other sources but is lower than those of poudrette after 6 months' trenching. The details are available, but have been omitted in the interest of space.

Nitrogen content varies considerably. There is a remarkably high lime content. A low phosphate content was noted in the Malwa Bhil Corps product; this is perhaps due to the simple diet of the sepoy.

The manure has so far been used at the institute and by cultivators for cotton, jowar (sorghum), wheat, sugar-cane, potatoes, Indian and

TABLE IV
Labour employed

Disposal ground	AVERAGE DAILY INTAKE		Number of men	Total daily wages
	Refuse, cubic feet	Night-soil, gallons		
Indore City	2,025	1,313	22 and 1 foreman	Rs. 8-9-7
Indore Residency Area	366	420	3	Re. 1-2-0
Malwa Bhil Corps	90	120	2 *	" 0-12-0
Neemuch Cantonment	700	1,040	7	Rs. 2-4-0

* These men do the sweeping and collection of refuse and night-soil in addition.

(h) *Initial costs.*—The economy of space and the low installation costs are evident from the following table :—

European vegetables and extensively in private gardens for flowers. The results were everywhere satisfactory.

TABLE V
Installation costs and space economy

Disposal ground	Total trench length, feet	Daily intake refuse, cubic feet	Population served	Cost of installation, Rs.	SPACE REQUIRED	
					Old process, acres	New process, square feet
Indore City	1,200	2,025	60,000	4,600 †	25	134,200
Indore Residency Area	240	366	4,400	222	1.3	12,000
Malwa Bhil Corps	100	90	1,000	*	1	3,000
Neemuch Cantonment	280	700	800	200	*	14,000

* Not available.

† Including Rs. 2,000 for roads and Rs. 1,000 for revetments and partitions.

(j) *Manurial value of the compost.*—The residual value of poudrette has been mentioned

In quantitative experiments on lucerne and wheat the yields were :—

TABLE VI
Response of lucerne and wheat to composts
A. Yields in pounds per acre of lucerne (3 cuttings)

	Farm compost (47.3 per cent moisture)			Habitation-waste compost (33.7 per cent moisture)

Yields in lbs.						
Quantity of nutrients added per acre in lbs.—						
Nitrogen	50.8	101.5	152.3	49.8	99.7	149.5
Phosphate (P ₂ O ₅)	48.1	96.2	144.2	95.1	190.3	285.4
Ratio N. : P ₂ O ₅		1 : 0.95			1 : 1.91	

TABLE VI—*concl'd.*

B. Yields of wheat—grain and straw—in pounds per acre.

	FARM COMPOST			HABITATION-WASTE COMPOST			AMMONIUM SULPHATE		
	1 unit N.	2 units N.	3 units N.	1 unit N.	2 units N.	3 units N.	1 unit N.	2 units N.	3 units N.
Grain	1,325	1,463	1,829	1,310	1,757	1,886	1,037	1,080	1,210
Straw	1,526	1,708	2,117	1,430	2,147	2,162	1,244	1,352	1,472
Quantities added per acre in lbs.—									
Nitrogen	36.7	73.4	110.2	36.7	73.4	110.2	36.7	73.4	110.2
Phosphate (P ₂ O ₅)	33.8	67.6	101.3	67.2	134.4	201.6
Ratio N. : P ₂ O ₅		1 : 0.92			1 : 1.83				

The phosphorus content of habitation-waste compost is in this instance almost twice that of farm compost made from plant residues and this obviously accounts for the superior yield of lucerne treated with the former. With field crops at Indore such as wheat no appreciable difference has appeared, and the nitrogen-phosphate ratio in both seems to be adequate. The suitability of habitation-waste compost even for ordinary crops is clear. The low yields with ammonium sulphate may be due to want of phosphate, or more probably to more rapid exhaustion of available nitrogen.

There seems every reason to suppose that the process will be suitable for a wide range of climates and agricultural conditions. In western countries it is probable that it will suit the needs of small communities, while the cities with sewage systems can utilize their sludge to convert the refuse to manure. No doubt labour-saving devices and mechanical aids will have to be evolved where large quantities are to be handled, and the cost of labour is high.

The writers believe it can be claimed, without exaggeration, that the Indore process for the disposal of habitation wastes is much simpler and more economical than any other process so far attempted. It supplies a ready and practical means of preventing that prodigious waste of fertilizing substances which has hitherto increasingly characterized all stages of human civilization, while, at the same time, it constitutes a real advance in sanitation, providing a cheap and profitable solution of the refuse-disposal problem which is still imperfectly solved in most communities in the world. Sanitation need no longer be a luxury confined to large and prosperous towns.

Acknowledgments.

Without the co-operation and willing assistance of Lieut.-Col. J. R. J. Tyrrell, C.I.E., I.M.S. (ret'd.), Director of Public Health and Sanitation, Indore State, and of Lieut.-Col. R. F. D. Megregor, I.M.S., and his successor Lieut.-Col. M. E. Nicholson, I.M.S., Chief Medical Officer in Central India, the process described could not have been developed for lack of facilities.

To Mr. A. W. H. Dean, Executive Engineer, C. I. Agency, Mr. Prabha Dayal, Superintendent, Civil Area, and to Rai Sahib Dr. Ram Sahai, Sub-Assistant Surgeon in the C. I. Agency, the writers' thanks are due for the readiness with which their suggestions have been adopted and for the care with which records have been kept and in equal degree they are grateful to Dr. Bhargave, Executive Health Officer, and his staff on the Indore Municipality.

Capt. R. M. Lindsley, Commandant of the Malwa Bhil Corps, and Dr. Blunt, Sub-Assistant Surgeon, have shown how well suited is the process to the needs of rather small detachments of troops while Capt. W. B. MacEvoy, I.M.S., at Neemuch, C. I., is demonstrating its adaptability to cantonment conditions. Their careful recording of data has been of much value.

Summary

(1) The present efficiency of disposal and utilization of habitation wastes, affecting a considerable portion of humanity, is discussed.

(2) Its importance to agriculture has been emphasized.

(3) Recent attempts to solve the problem have been reviewed.

(4) The essentials of an improved system for general adoption are given, the futility of attempts at full nitrogen conservation in practice being emphasized.

(5) The main features, advantages and the mode of operation of the Indore process are indicated.

(6) Quantitative relations of wastes and compost, its cost and agricultural value, and the scope for the application of the process have been shown.

APPENDIX

DETAILED TECHNIQUE

Installation.—The essential part is the charging trench, which should be fifteen feet wide, and two feet deep. The floor must slope gently along its length to prevent water-logging, and must discharge into a natural drainage channel. It must be served by a road to be used as a charging platform running alongside. This

road may lie between two trenches, serving each, and usually the most economical construction is to dig the trenches one foot deep and pile enough of the excavated earth to make the road foundation. The road should be at least fifteen feet wide (preferably twenty feet) and suitably metalled to stand carting in wet weather. The side of the trench against the road must be vertical and should be reveted with timber or a wall of stone or brick, the top of which should carry a sill of suitable material (e.g., old steel rails, girders, or heavy logs) against which carts can back. Without this sill a log must be put in position at each tipping.

The other side of the trench is to be bounded, preferably by a partition, the top half of which is removable—old sleepers, boards, logs, or thick corrugated iron sheet between upright posts—or by an earth, stone or brick wall, rising two feet above the trench floor. Beyond this partition about twenty feet space must be left for storage; in practice extensive sales of compost are usually confined to two or three periods of the year. This storage ground may be excavated level with the bottom of the trench if desired. Unless dug on solid stony ground the trench must always be floored with road metal or at least well-rammed brick-bats and rubble; the storage ground is also better so treated. It is wise to build an earth bank with a drain on those sides of the whole installation from which the flow of surface water is to be feared.

The total length of charging trench required is determined by the average daily quantity of refuse received. Experience has shown that for each cart-load* of refuse received daily, 1 foot 4 inches length of trench is necessary. The volume of night-soil received has no influence on this figure as it is taken up in the interspaces.

Charging the trench.—The first charge should be made so as to leave a vacant space of four feet at one end of the trench. To start with, cart-loads of refuse, without sorting, are tipped in from the charging platform and spread by drag rakes (figure 2) to make a

Fig 1—Charging the trench.

layer three or four inches thick. About a dozen forkfuls of inoculum from a charge at least two weeks' old is then scattered (this of course is not necessary for the first charges of a new installation) and the cartful of night-soil tipped on top, followed immediately by more refuse, tipped over the night-soil. Then the refuse, together with the night-soil below, is drawn by drag rakes in small lots until the breadth of the trench opposite is covered. About four layers per day should be made thus until the whole depth is charged in two days. The top layer for the day

and at the end of the charge should be refuse only, without being mixed with the night-soil layers beneath. This top layer should not be more than 1 inch to 2 inches thick, being intended as a coating to preserve

Fig. 2.—Spreading the charge.

uniform moisture and heat in the whole mass of the mixture, and to prevent the breeding of fly larvae on top. The next charge should be given to the adjacent portion of the trench without any interspace and so on continuously.

Proportion of night-soil to refuse.—No proportioning is necessary; whatever quantities of refuse or night-soil arrive must be treated at once, no excess of either being left over. If the proportion of night-soil is high or of a very liquid nature, the refuse layer should be spread with a surrounding raised margin until the mixing is complete. After the charge or the later turns the heaps must have flat tops and vertical sides, otherwise difficulty will arise in preventing water-logging in a wet season and in keeping uniform moisture during dry weather.

First turn.—Two days after charging is finished the first turn is given—i.e., four days from the start. A four-pronged garden digging fork has been found very suitable for this; see figure 3.

While this is being done water should be distributed from a hose or by hand upon the turned material so

Fig. 3.—The first turn.

as to soak it without permitting seepage or local water-logging. Sullage water may well be applied to the lower layers at this stage but on no account to the surface.

* A cart-load of refuse is here taken as 35 cubic feet and a cart-load of night-soil as 60 gallons.

The few fly larvae that may be found on the cool sides of the charge are turned into the heap and destroyed by the high temperature therein. If the first turn is delayed beyond four days there will be a greater development of maggots and more chance of their escaping to pupate in crevices in the walls or floor of the trench, especially in wet weather. Such pupation is usually slight and if desired can easily be checked by disinfectants.

Second turn.—The second turn is given eight days later by forking the charge over to the opposite side of the trench, adding water if necessary.

Fig. 4.—The second turn.

Fig. 5.—The third turn.

Third turn.—This should be given from eight to fifteen days after the second turn according to the stage of decomposition—when the material has crumbled to a fairly advanced degree. The mass is forked out of the trench (with watering as necessary) on to the adjacent storage ground where it may be heaped up to four feet in height.

Watering between turns.—During very hot or windy weather the upper layers may become too dry; a well-distributed surface watering should then be given.

Duration of the process.—The manure will be ready for use in from three to eight weeks after charging, the period depending on the proportion of night-soil to refuse, the correct control of moisture and air throughout and the season.

Precautions during monsoon rains.—The initial charge should not occupy the full width of the trench; a two-foot space should be left next to the partition to allow storm-water to flow. If there is risk of water flowing

into the trenches from the road the charge should be built up a foot higher, above road level. In a trench of considerable length there may be a danger of exposed corners of the heap being washed away by drainage water on the trench floor. This can be prevented by protecting such surfaces with strips of sheet iron about three feet long and suitable height. During prolonged rains it is advisable to give the third turn earlier, to prevent water-logging and slowing down decomposition.

Implements necessary.—One drag rake with four seven-inch blunt steel tines and a long handle, and one fork will be needed to deal with a daily intake of five cart-loads of refuse.

The sprinkling of water to ensure good distribution may be done, on a small scale, by throwing it with a suitable vessel such as *tagari*. For larger installations a hand pump with a hose and sprayer or even a permanent supply of piped water would be more efficient.

Medical News

MALARIA RESEARCH AND THE MALARIA COMMISSION OF THE LEAGUE OF NATIONS

This year malarialogists will have noticed the appearance of several important reports published by the Malaria Commission of the League of Nations, or under its auspices.

Organized ten years ago, the Malaria Commission began by studying the epidemiology of malaria as well as all the methods of malaria control employed in different countries in many of which the disease had assumed epidemic proportions as a result of the world war.

The first two reports of the Commission, published in 1924 and 1927, therefore deal with the epidemiology of malaria in the countries in which investigations had been carried out on its behalf, and on the principles governing the prevention of malaria. The third general report of the Commission, published this year, deals with the therapeutics of malaria and describes the present status of our knowledge of the treatment of the disease and the opinions of the Commission on methods of applying that treatment.

A report on housing and malaria by Christophers and Missiroli deals with a problem that was taken up by the Commission in 1928. Another subject, malaria in the deltas of large rivers, has been investigated for several years by members of the Commission. Reports have been published on the deltas of the Danube, the Ebro and the Rhine, followed by a memorandum on certain general considerations on the problem. In these papers has been summarized our present knowledge on these three subjects, but as that knowledge is still far from complete, and malaria research still actively in progress, the Commission feels that lines of further investigation should be indicated in order to point out the problems most urgently calling for solution.

The full list of questions on which the Commission recommends that research should be undertaken is given below. It will be noted that all the problems are classified under the three subjects which have been investigated for many years, viz, treatment of malaria, housing and malaria, and malaria in deltas.

The study of these problems is not the monopoly of the League Malaria Commission. The members of that Commission feel strongly that they should draw the attention of investigators all over the world to the importance of these problems. No malarialogist denies that malaria is essentially a local problem; no countries are alike as regards malaria. Therefore, the results of any investigation applies as a rule only to the country where it was made, and, if conclusions of a more general value are to be reached, the observations and controlled experiences of different national investigations should first be pooled.

For example, immunity to malaria varies, of course, according to the greater or lesser opportunity of repeated infection, to the virulence of the strain, to the number of sporozoites inoculated, and so on. Malaria therapy offers a good opportunity for the study of this problem, but it is of the greatest interest to know if a strain of, let us say, *P. vivax*, which has proved very virulent in England, has the same virulence in Roumania, or in Italy; or if a Roumanian strain towards which patients have become immune in Roumania, as the result of repeated inoculation, protects against the English strain, and vice versa.

The international co-ordination of research into malaria has proved to be of the greatest value; to carry it out, however, would be difficult, if not impossible, without the existence of an international organization of some sixty members and corresponding experts like the Malaria Commission of the League.

The following is the list of questions recommended for further investigation:—

I. Treatment—clinical and therapeutical research work:

Determination in hyperendemic and endemic regions of the age groups most seriously affected by the disease and consequently requiring most attention in the matter of treatment. Investigations should cover in the first place the indigenous population and then be extended to immigrants.

Determination of the minimum dose of quinine sufficient for the treatment of the disease in hyperendemic and endemic areas where the natives have attained a certain degree of immunity.

Ascertainment of the dosage (by age groups) of plasmodium sufficient to prevent the gametocytes from infecting the anopholes and the intervals (per week) at which it should be administered.

Determination of the extent, if any, to which the therapeutical action of quinine is increased by the administration of plasmodium (combined medication).

A beginning should be made with laboratory research on cases of induced infection before proceeding to apply this method in the field.

Continuation of clinical tests with both types of 'totaquina' in accordance with the method laid down in the report.

Experiments in malaria control by means of medicaments alone without the application of anti-anopheline measures.

Blackwater fever: investigation of the relations between quinine and blackwater fever by means of experiments on animals (malaria in monkeys).

Housing and malaria.—Biology and geographical distribution of the different varieties of *Anopheles maculipennis*.

Study of the following species of tropical anopholes from the point of view of a possible differentiation of races:

(a) *A. hyrcanus* and its several varieties (though widely disseminated, this strain is not as a rule very dangerous, though it may become so in certain countries, and especially Sumatra).

(b) *A. bifurcatus* (unimportant in Europe, but dangerous in Palestine).

(c) *A. ludlowi* var. *sundaicus* (dangerous everywhere, though there is a great difference between its breeding places on the coast of Java and in the interior of Sumatra).

(d) *A. gambiæ* (dangerous everywhere, though its breeding places differ in the Union of South Africa and Tropical Africa).

Causes of the very great variations met with in the distribution of malaria in certain tropical regions—such as the phenomenon of immune areas in the immediate vicinity of hyperendemic areas—and in particular the possibility of a relation existing between this phenomenon and the deviation of the anopholes.

Investigation of the factors which make certain rice-growing areas highly subject to malaria while others remain immune.

Study of the African anopholes and the connection between the various species of anopholes and malaria in Africa.

Malaria in deltas.—Initiation or pursuit of research on the varieties of *A. maculipennis* found in European deltas in connection with malarial foci (Danube, Ebro, Rhine, Rhone, Po).

It is suggested that Indian, Siamese and Indo-Chinese malarialogists might usefully conduct similar investigations with regard to the races of malaria-carrying anopholes in the deltas of their respective countries.

Investigation of the influence of agriculture on the domesticity of anopholes and on malarial endemicity.

Study of live stock in connection with local anophelism and the disease.

Historical study with special reference to malaria, of variations in the topographical and demographical characteristics of deltas.

Investigation of the degree of susceptibility to malarial infection of inhabitants of deltaic areas.

ACTA AEROPHYSIOLOGICA

The new periodical *Acta Aerophysiologicala* is dedicated to research work concerning the influence of aeronautics and mountaineering on man. It deals with very practical problems, as flying, from being an occupation of few, is gradually becoming a sport for many. For all those who are interested in aeronautics, accurate information on the influence of flying on the human body is of prime importance.

This periodical intends to deal with those problems on an international basis. In almost all countries of the world special collaborators have promised to assist. The first issue shows the importance of the new series. In about a hundred pages different subjects connected with the medicine of aeronautics are dealt with in many interesting and profusely illustrated essays.

The editor of the *Acta Aerophysiologicala*, Prof. Dr. Ludolph Brauer, Director of the 'Allgemeines Krankenhaus' Hamburg-Eppendorf, has succeeded in making the periodical so interesting that a wide circulation may be confidently expected.

The paper is published by Broschek & Co., Hamburg 36, and sold by Conrad Behre Hamburg 1, Kleine Johannisstrasse 19, where the first issue may be ordered for RM 3. and further information concerning the periodical may be obtained.

ABSTRACTS OF THE MINUTES OF A MEETING OF THE BENGAL COUNCIL OF MEDICAL REGISTRATION, NO. 67, DATED THE 27TH JULY, 1933

GOVERNMENT of Bengal Notification announcing the election of the undermentioned gentlemen as members of the Bengal Council of Medical Registration was recorded:—

Dr. Bhupendranath Bandyopadhyay, L.M.P.
Dr. Amulyadhan Mukhopadhyay, L.M.F.
Rai Sahib Dr. Prabodhehandra Ray, L.M.P.
Lieut.-Col. N. C. Kapur, I.M.S., *vice* Major S. N. Mukherjee, I.M.S., deceased.

Government of Bengal Notification announcing that the possession of the M.B., B.S. degree of the Rangoon University should entitle any person to have his name entered in the Register of Registered Medical Practitioners maintained in Bengal was recorded.

The undermentioned gentlemen were nominated representatives of the Council and the Governing Body of the State Medical Faculty of Bengal on the Bengal Sanitary Board:—

(a) Dr. Taraknath Majumdar, L.M.S., D.P.H., D.T.M., F.C.S., F.R.S.E.

(b) Dr. T. Ahmed, M.B., D.O.M.S., F.R.C.S.

It was decided that the undermentioned schools be inspected during the next six months:—

(a) Dacca Medical School.

(b) Lytton Medical School, Mymensingh.

(c) Calcutta Medical School.

(d) Jackson Medical School, Jalpaiguri.

Motions to the following effect by Dr. Amulyadhan Mukherjee, L.M.F., were considered, and decisions taken as indicated below:—

(a) (i) That a committee be appointed to inspect medical examinations of the State Medical Faculty of Bengal.

(ii) That legal opinion be taken as to whether the Council has power to inspect medical examinations held by the universities.

The motion was modified by Dr. K. S. Ray, M.B., Ch.B., and passed as modified.

(b) That Government be requested to put a stop to the continuance of unauthorized medical schools which turn out a large number of bogus medical men with positive mischief to the community and the profession. Passed.

(c) That employment of unregistered practitioners by local self-governing bodies be put a stop to, as contrary to the provision of section 31 of the Bengal Medical Act. Passed.

(d) That the maximum number of students fixed to be kept in recognized medical schools be calculated on an average basis during session July to June.

This motion was referred to the inspection committee for consideration and report.

Entry of the qualification D.M.R.E. (Cantab.) was sanctioned under section 21 of the Bengal Medical Act, 1914, against the name of Dr. Pareschandra Chakrabarti.

Entries of the qualifications, D.T.M. & H. (Cantab.), D.T.M. & H. (R.C.P.S.) and D.T.M. (Liverpool) were sanctioned under section 21 of the Act against the names of Drs. Jitendramohan Ghosh, Mohan Chand Madhok and Shrikant Shamsar Singh, respectively.

The Registrar's report that Satishchandra Datta was convicted under section 5 of the Indian Medical Degrees Act, 1914, and sentenced to a fine of Rs. 100 by the Deputy Magistrate of Dacca was recorded.

In connection with an application for the recognition of the Bengal Medical Institution and Hospital, Beliaghata, Calcutta, the principal of the institution was directed to furnish information on the return form prescribed by the Council and the return submitted was referred to the standing inspection committee for consideration and necessary action.

The Council expressed sorrow at the sad and untimely death of Major S. N. Mukherjee, I.M.S., a member of the Council for a number of years and resolved to send a message of condolence to Mrs. Mukherjee.

THE INDIAN HONOURS LIST

1ST JANUARY, 1934

The following are the names of medical workers in the Indian Honours List of date 1st January, 1934. We offer them our congratulations.

C.I.E.

Lieutenant-Colonel A. D. Stewart, Director, All-India Institute of Hygiene and Public Health, Calcutta.

Lieutenant-Colonel R. N. Chopra, Professor of Pharmacology, School of Tropical Medicine, Calcutta.

Kaiser-I-Hind Gold Medal

Miss A. I. Burton, Lady Superintendent, Minto Nursing Association, Murree.

Miss C. Falkiner, Lady Superintendent of Nursing, Medical College Hospitals, Calcutta.

Mr. S. P. Shroff, Eye Specialist, Delhi.

Kaiser-I-Hind Silver Medal

Miss M. Bazeley, St. Stephen's Mission Hospital, Delhi.

Miss J. Hogg, Mure Memorial Hospital, Nagpur.

Miss E. B. Holloway, Lady Dufferin Hospital, Bettiah, Bihar and Orissa.

Sister M. I. Lundin, King George's Hospital, Vizagapatam.

Miss A. M. Quinn, Lady Lyall Maternity Hospital, Agra.

Mr. Bepin Bihari Brahmachari, Director of Bengal Public Health Laboratory, Bengal.

Mr. B. A. Irvine, Governor's Staff Dispensary, Bengal.

Khan Sahib

Muhammad Maizuddin Khan, Assistant Surgeon.

Rai Sahib

Babu Ramesh Chandra Ganguli, Civil Assistant Surgeon, North Lakhimpur, Assam.

FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE. 9TH CONGRESS

THE 9th Congress of the Far Eastern Association of Tropical Medicine will be held at Nanking, China, from the 2nd to the 8th October, 1934.

All licensed medical, dental and veterinary practitioners are eligible for membership. The membership fee for the period 1930-1934 is £3 and should be paid to the local provincial secretaries of the Far Eastern Association of Tropical Medicine, to whom the names of members in their areas should be submitted. The members are also requested to inform the local secretaries

whether they propose attending the conference. The titles of any papers which it is proposed to place before the conference should be submitted to the local secretaries at an early date. Arrangements will be made for the reading at the Congress of any paper submitted by a member who is unable to attend.

Further information may be obtained from the local provincial secretaries or from the local secretary for the Government of India, Malaria Survey of India, Kasauli, Punjab, British India, or the Honorary General Secretary, Far Eastern Association of Tropical Medicine, Batavia-Centrum, Java.

Current Topics

Anæsthesia in Midwifery: A London Experiment

(From the *British Medical Journal*, 11th November, 1933, p. 884)

THE London County Council sanctioned in the early part of last year the experimental engagement of six extra assistant medical officers for the purpose of administering, in the Council's hospitals, light anæsthesia in normal labour. The six officers took up their engagements in July 1932, and the engagements, originally for six months, have since been three times renewed. The choice of anæsthetic was left to the discretion of the medical superintendent, and chloroform, gas and oxygen, ether and ethyl chloride, and nembital, alone or in combination with sedatives, have all been given extensive trial. In the eight hospitals to which special anæsthetists were for varying periods attached 3,729 patients were delivered under light anæsthesia up to April 1933. The unanimous opinion of the medical superintendents of these hospitals is that a properly chosen and administered anæsthetic does not materially delay labour and has no detrimental effect on mother or child. At one hospital only was it considered that a slight, but definite, delay occurred. Even at two hospitals originally selected which were found unsuitable for the experiment, and from which the anæsthetists had to be withdrawn, no actual detriment to the patient was alleged. In only two cases in the whole series was it suggested that a necessity for forceps might have been due to the anæsthetic. Of other complications associated by certain obstetricians with the use of maternal anæsthesia there has been no trace, nor has any increase of puerperal morbidity been noted in any hospital.

As for the relative merits of the anæsthetics employed, it is reported that no one method stands out from the others, but all have their advocates. The records have incidentally shown the great value of analgesics in labour. The skilful administration of chloral or morphine, alone or in combination, has proved invaluable for conserving the patient's strength, diminishing fear and shock, and blunting the recollection of labour. In April 1932, the use of crushable chloroform capsules containing 20 minims of chloroform was sanctioned. The use of these was ultimately adopted in fifteen of the Council's hospitals, and has become increasingly popular. All the hospitals concerned, with one exception, presented a favourable report. Out of 1,121 patients whose opinion was recorded, 613 considered the capsules of great use, 446 of some use, and only 62 reported that they had been of no use. In no instance was it alleged that their employment led to the application of forceps. The only substantial disadvantage was found to be that a number of patients were noisy and difficult to control, a trouble easily surmounted under hospital conditions, but a serious consideration for midwives in private practice. The

administration of the capsules has been delegated to the maternity sisters and their deputies under certain defined conditions. They were administered in 2,643 cases.

In a report on the experiment the Central Public Health Committee states that anæsthesia in labour is still outside the experience of the class of woman coming into municipal hospitals, and to many of them it is associated with obstetrical disasters. The suggestion of its use arouses a fear that the doctor anticipates an abnormal labour. There is also a curious belief current that a woman is doing something morally wrong in evading the pain of labour. By the women who manage to overcome their initial fears anæsthesia is received with deep gratitude. As a result of two years' experience, during which period a total of 4,540 cases (including the 3,729 delivered at hospitals to which special anæsthetists were attached) have received light anæsthesia in normal labour, it is considered that the experiment has justified itself. The demand from the women concerned was sufficiently strong and widespread to make the offer of some form of anæsthesia in normal labour an urgent public question. The obstetrical difficulties were much less than anticipated, though the administrative difficulties were greater, for the irregular distribution of the births over the twenty-four hours made it impossible to ensure that an anæsthetist was always available, and this form of administration is not readily combined with other duties. It is considered that the use of crushable chloroform capsules or some safe and simple equivalent should be relied upon as the usual method of anæsthesia for normal cases, where the medical superintendent is willing to delegate this duty to the senior nursing staff. The duty of administering or supervising the administration of analgesics and anæsthetics should be regarded as part of the normal duty of a medical officer in charge of the maternity ward.

Present Status of Various Spinal Anæsthetics and their Clinical Usefulness

By F. W. MARVIN, M.D.

(Abstracted from the *Journal of the American Medical Association*, 4th November, 1933, Vol. CI, p. 1475)

As a result of its satisfactory employment in both the bad and the poor risk cases for operative procedures, spinal anæsthesia became at first tolerated, later accepted, and now appreciated. The hazards of spinal anæsthesia have been so largely overcome and its noxious effects on the circulation have been placed under so much better control that its use in surgery is fully justified. Hence, it behoves one to use it frequently in the good operative risks. This change is gradually taking place, so much so that the old fallacy of using spinal anæsthesia in only poor general

risks or nearly moribund patients should be practically extinct.

Statistics both here and abroad show that subarachnoid block is becoming more popular through its continuous use in clinics which are staffed with anaesthetists specially trained and experienced in its use.

The use of spinal anaesthetics requires an accurate and precise technique for uniform results. I strongly

(benzoyl-gamma [2-methylpiperidine] propanol hydrochloride), nupercaine, and pantocain (para-butylamino-benzoyl-dimethyl aminoethanol hydrochloride).

The relative toxicity of these drugs as observed clinically are, in the order named: nupercaine, neothesisin, procaine hydrochloride and pantocain. The reactions peculiar to these drugs may be summed up briefly as depicted in the table below:—

	Posterior root block	Anterior root block	Change of blood pressure		Heart rate	Respiratory depression	Nausea	Headache
Procaine hydrochloride.	Immediate	Immediate	Definite drop 20 to 30.	initial	Slight slowing.	No	No (small doses).	No
Neothesisin ..	Slight delay	Slight delay	Definite drop 20 to 30.	initial	Slight slowing.	Appreciable	No	No
Nupercaine ..	Delayed	Delayed	Definite drop 30 to 50.	initial	Marked slowing.	Change	Slight	Few reported.
Pantocain ..	Immediate	Immediate	Appreciable drop 0 to 10.		No change	No	No	No

advise every one to employ his own technique in his own clinic. Not every new method that comes along should be adopted. If an anaesthetist has good results he should continue with his technique but, on the other hand, he should not be contented to squat and ignore the newer and better preparations with the improved methods of application.

Drugs formerly used in spinal anaesthesia are now being replaced by newer and less toxic ones which give better and more satisfactory anaesthesia. Nearly every drug employed as a local anaesthetic has been injected into the subarachnoid space. Forty-nine years ago, cocaine was the first local anaesthetic introduced. The high toxicity of cocaine precludes its use in spinal anaesthesia. It is said, however, as a standard to gauge the toxicity of the other drugs. Cocaine, having fallen into disuse, was supplanted by several drugs, of which I shall mention tropacocaine hydrochloride, stovaine, procaine hydrochloride and others.

Tropacocaine hydrochloride has been used quite extensively in the past. It has a toxicity about half that of cocaine, but its duration of action is much shorter. To be effective, it must be used in a fairly concentrated solution. Because of its high toxicity and rather uncertain analgesia, tropacocaine hydrochloride has been gradually discarded.

Stovaine, prepared by Fournneau in 1904 and brought into general use by Barker in 1906, has enjoyed great popularity, especially in France. It is powerful, and it produces marked muscular relaxation. There are, however, certain disadvantages in that it is more irritating to the connective tissues and nerve fibres. Headaches of rather severe intensity are noted frequently after its use. It deteriorates rapidly and must be kept in special containers.

Spinocaine (a brand of procaine hydrochloride with strychnine sulphate), introduced by Pitkin six years ago, gained a wave of popularity at first but of late it has been more or less replaced by procaine hydrochloride. The fact that it is of lighter specific gravity than the spinal fluid caused several accidents, which could have been avoided had more care and precaution been used and had better instruction been given as to its installation. The claims made for its very complete control are plausible, but I have not used it for the past three years.

Toxicity is the first question that surgeons ask whenever a new drug is introduced into a clinic. The Boston City Hospital has adhered always to the principle of having a complete knowledge of the toxic action of these drugs, which have been furnished by the manufacturer and carefully checked up by the hospital's research department. After a careful survey and use of the several drugs, we confined our study to the following four: procaine hydrochloride, neothesisin

A comparison of these drugs as to their relative difference in dosage and the length of anaesthesia that they produce is below:—

Drug	Dosage	Duration of anaesthesia
Procaine ..	200 mg.	One hour.
Neothesisin ..	160 "	Ninety minutes.
Pantocain ..	20 "	Two hours.
Nupercaine ..	10 "	Three hours.

The clinical usefulness of these drugs might well entail a lengthy discussion, but space will not permit. I shall enumerate briefly what I consider the practical use of these drugs: All operations below the diaphragm may be performed under spinal anaesthesia. Apparently there is no limitation to the number of spinal anaesthetics that a patient may undergo. To substantiate this statement, I have an authentic report that spinal anaesthesia was administered ten times within a period of fourteen months to one patient without any apparent deleterious effects.

Genito-urinary surgery offers a field in which we use spinal anaesthesia as a routine, so satisfactory have been our results. Prostatectomies are performed with very small doses of the anaesthetic drug. For example, we never use more than 60 (usually 50) mg. of procaine hydrochloride. When pantocain is used, the dosage varies from 8 to 10 mg. with satisfactory anaesthesia. The first stage operation (a double vasectomy and cystotomy) with procaine hydrochloride shows a drop in blood pressure. The second stage, performed two weeks later with pantocain, shows no drop in blood pressure. To substantiate further the clinical usefulness of these drugs in genito-urinary surgery I shall illustrate with cases in which there were definite complications other than the genito-urinary pathologic changes. A second stage prostatectomy was performed on a man, aged 78, who had endocarditis and myocarditis, with a previous history of six anginal attacks. We advised the first stage under local anaesthesia and the second stage under spinal anaesthesia using pantocain. In a case of renal calculi of the left kidney in a woman who was four months pregnant and weighed 180 pounds (81.6 Kg.) and was 5 feet (152.4 cm.) tall, the stones were removed, and she expects the baby next month. Another satisfactory case in this group was that in which an octogenarian in his eighty-fourth year had a bladder stone the size of a goose egg and a prostate larger than a lemon removed under pantocain.

The relaxation afforded by spinal anaesthesia renders operative procedures less difficult and minimizes the

shock. The safety of these drugs as compared with general anesthetics is highly desirable in genito-urinary surgery because they do not seriously interfere with the kidney function.

Abdominal, gynecologic and orthopedic surgery of the lower half of the body vary a great deal in their types of operations and the length of time they consume. The use of spinal anesthesia in obstetrics may be dismissed with the statement that we do not advise its use unless a definite pathologic complication exists. We have used it seven times during the past year in private cases without a fatality. All of the patients had definite pathologic conditions of the chest.

All four of these drugs have been used on both males and females; the youngest patient was a girl, aged 8 years, while the oldest was the octogenarian. Their weights varied from 70 to 340 pounds (31.8 to 154.2 Kg.). Gastric and intestinal surgery of all types, including resections for carcinoma, are included in our series. Carcinoma of the sigmoid was completely removed in one stage. A right colectomy was done with anastomosis of the terminal ileum to the transverse colon. This patient is well and working. Gallbladder surgery was performed with great ease, as were the long and tedious umbilical and ventral herniotomies. We have a large series of the so-called double operations in gynecology. Included in the orthopedic operations may be mentioned two spinal fusions and many fractures, including one patient who had both femurs broken. All surgery of the lower extremities, including diabetic cases, and the different circulatory diseases in which spinal anesthesia was given for diagnosis, was performed under spinal anesthesia with satisfaction.

CONCLUSION

We have used each of these drugs in our series at the Boston City Hospital during the past sixteen months without a fatality. These drugs have been used separately and in different combinations for very definite purposes, with the result that we have formed a strong opinion that it is not necessary to mix them. We advise the use of them separately for each individual case. Procaine hydrochloride and pantocain are the drugs frequently employed. Of these two drugs, pantocain offers everything that procaine hydrochloride will accomplish and has the advantage that it does not lower the blood pressure as does procaine. Furthermore, clinically, it is apparently less toxic than procaine hydrochloride, besides producing a longer and more satisfactory anesthesia.

Empyema

By J. W. LINNELL, M.C., M.D., M.R.C.P.

(Abstracted from the *Medical Press and Circular*, 4th October, 1933, New Series, Vol. CXXXVI, p. 321)

(1) WHEN TO DRAIN

EMPHYEMATA can be caused in a multitude of ways and through the agency of many kinds of infecting organisms, but it is only with the two commonest types, those complicating the pneumococcal and streptococcal pneumonias, that we shall deal. There is a very great difference in their development and course. It is ignorance of this fact that results in the principles of treatment commonly and correctly applied to the one being so often applied to the other—with disastrous effects.

Broadly speaking, a pneumococcal empyema is 'meta-pneumonic', i.e., it develops *after* the subsidence of the acute pneumonic process in the underlying lung. A streptococcal empyema, the type usually met in influenza epidemics, on the other hand, is 'syn-pneumonic', i.e., it develops simultaneously *with* the pneumonic process in the underlying lung. In pneumococcal cases adhesions form rapidly between the two layers of the pleura at the margins of the effusion; the

latter is thereby walled off early from the general pleural cavity and, moreover, rapidly develops into thick 'laudable' pus. In streptococcal cases the adhesions take much longer to form, and the effusion, besides being more copious, remains thin and seropurulent for a very considerable period.

In pneumococcal cases, at the time of the commencement of the suppurative process in the pleural cavity, the antibodies are in the ascendant, the system is no longer grossly poisoned, the temperature has usually been down for some days, and the patient is comparatively well. In streptococcal cases, at the time of the onset of the empyema, the antibodies are not yet mobilized, the system is still severely poisoned, the temperature is still high, and the patient is usually desperately ill, dyspnoic, and cyanosed.

To drain early in a pneumococcal case is nearly always safe, for it usually means no more than the evacuation of a well localized abscess in a comparatively fit subject. To drain early in a streptococcal case is often disastrous, for it means producing a more or less complete pyo-pneumothorax and submitting a patient already in a precarious state to all the added dangers connected with such a condition.

What then is the proper treatment of a streptococcal case? Surely it is to help tide the patient over the acute pulmonary condition, relieving any distress that may arise meanwhile through the size of the effusion by aspirating, until here, too, a well localized abscess containing thick pus ripe for evacuation has developed. Arguments such as these were brought forward in the celebrated report of the American Empyema Commission which investigated the causes of the high mortality rate obtaining in cases of empyema during the big epidemic of hæmolytic streptococcal infections of the respiratory tract in the military camps situated in various parts of the U. S. A. during the winter of 1917-1918. At the hands of the Commission the rate fell from 30.2 per cent to 4.3 per cent, and all over the world since then its findings have been verified by further experience.

In actual practice, whether the case be pneumococcal or streptococcal in origin (and we would insist that it is not always possible to be sure without laboratory facilities), the one indication that the time has arrived to drain is the finding of frank 'laudable' pus by aspiration. As a rule the necessary thickness can be easily gauged in a moment by inspection, but if there be any doubt on the subject, a sample of the aspirated fluid can be collected in a test-tube and allowed to stand for twelve hours; if then there is over 75 per cent of deposit, it is safe to resect a rib and drain. As a matter of experience the interval between the onset of the effusion and the development of frank pus in streptococcal cases is generally two to three weeks; on an average four aspirations are carried out in that time, and on each occasion enough should be removed to relieve distress.

Coming to the actual technique of aspiration, there are certain points to keep in mind. The site, for instance, should be chosen with a view to the future operation. On every occasion the tissues should be thoroughly anesthetized all the way down to the pleura; for this about 10 cubic centimetres of a 1 per cent solution of novocain are required. If much fluid has to be withdrawn, a two-way stop-cock attached to an ordinary 20 cubic centimetre syringe will be found of considerable assistance, and a rubber connecting-tube between the syringe and the needle will prevent the latter from being pushed in and out if the patient moves.

It is curious how comparatively seldom repeated aspirations of streptococcal pus cause anything but trifling infection of the chest wall. Nevertheless, severe cellulitis does occasionally result, especially if there be a superadded anaerobic infection; and even a mild inflammation may be a source of considerable pain to a nervous and debilitated patient. To obviate this Mr. Tudor Edwards has devised the following procedure,

which it may be well worth while to remember: After the first aspiration the line of the needle track is opened up with a sharp knife by an incision one inch long, which goes through the skin and muscles down to the level of the ribs. The wound is packed with vaseline gauze, and not only can future aspirations be performed through it without local anaesthesia, but the granulation tissue which develops in it generally forms an effective barrier against infection of the surrounding tissues, and when the time arrives for rib resection, it can be extended and used as the way of approach.

Whatever method of aspiration be used, directly the pus is found to be up to standard as regards consistency, operation should be no longer delayed. Adhesions form slowly in streptococcal cases, but once they form they organize quickly and tend to bind down the lung and delay re-expansion.

We do not propose to discuss the details of the operation and after-treatment in this paper, save as regards the removal of the drainage tube, but we should like to say that we do not regard them as matters of minor importance fit to be left in inexperienced hands. Failure to observe small points in technique can be the means of prolonging the patient's illness from weeks to months.

(2) WHEN TO REMOVE THE DRAINAGE TUBE

The tube should be so adjusted that its inner end is just inside the empyema cavity, after which it should be transfixed at the level of the skin with a safety-pin and maintained in position by affixing this to the chest wall with adhesive strapping. It is a common practice to remove the tube daily for cleansing; this is, however, quite unnecessary; once a week is often enough. The calibre of the tube may be reduced, but it is most important that it should not be finally removed till the lung has completely expanded and entirely obliterated the cavity.

It is well to estimate the size of the cavity from time to time in order to find how the obliterative process is proceeding. There are three simple ways of doing this: (a) introducing a gloved finger into it through the drainage opening; (b) probing it with a uterine sound, a soft metal gall-stone probe, or a urethral bougie; (c) making the patient lie in such a position that the drainage opening is its highest point, and then slowly introducing sterile fluid (e.g., boiled water) with a graduated syringe.

Statements to the effect that the tube prevents the lung from expanding, and that it should be removed as soon as the discharge is no longer purulent, are quite untrue; yet they are still, unfortunately, to be found in some of the textbooks. By far the commonest cause of chronic empyema is the removal of the drainage tube before the cavity is obliterated. In such cases pus re-accumulates, and sooner or later either discharges itself spontaneously through the old drainage site or has to be released by operation. Too often the doctor, not appreciating the real cause of the re-accumulation of pus, again removes the drainage tube too early, and the same story is repeated time and time again, the underlying lung becoming meanwhile imprisoned by a thicker and thicker layer of fibrous tissue, until in the end obliteration of the cavity becomes impossible without an extensive operation.

In conclusion, we would say that it is our experience that empyemata such as we have described, recognized early and treated efficiently, are usually completely cured under two months.

Nembutal in Labour A Record of One Hundred Cases of Nembutal and Chloral Narcosis

By FRED A. C. KELLY, M.R.C.S. (Eng.)

(Abstracted from the *Lancet*, 23rd September, 1933, p. 690)

THE following is an analysis of 100 consecutive cases of nembutal and chloral given to women in labour in

the obstetric unit at University College Hospital. Acting on the experience of O'Sullivan and Craner the following rules were formulated:—

A. Nembutal grs. 3 to be given to *primiparæ*: (1) when the os uteri is about three fingers' dilated and there are fairly strong pains at about five minutes' interval; (2) if the patient is distressed with strong pains, even if they are not occurring every five minutes, and the os three fingers' dilated.

B. Nembutal grs. 3 to be given to *multiparæ*: when the os uteri is about two fingers' dilated if there is distress. Nembutal grs. 1½ to be repeated once after three hours if labour is progressing and the pains are strong and regular. Chloral hydrate grs. 22 in all cases to be given twenty minutes after each dose of nembutal.

These doses vary a little from those given by O'Sullivan and Craner. They gave grs. 30 of chloral hydrate ten minutes after the initial dose of nembutal grs. 3, and their first repeat dose of nembutal grs. 1½ after two hours, and subsequent doses of both chloral hydrate and nembutal after three hours, up to but not exceeding a dose of grs. 7½ of nembutal in twelve hours. The modification in this series was considered advisable because the administration, timing, and dosing were left to the discretion of the labour ward sister. When it was found necessary to exceed the dose of nembutal, grs. 4½, medical permission was obtained. Chloroform or gas-and-oxygen was, with rare exception, given in all cases for delivery.

Women admitted in labour have, in normal cases, two vaginal examinations: on admission and when the membranes rupture. Therefore it is often difficult to state with accuracy the exact stage of dilatation of the os uteri when the first dose was given. For this reason in this analysis the times are worked out in hours before delivery.

In some cases, when the patients were admitted very early in labour before the pains were regular or frequent, 3 1 of the following mixture was given, in addition to a subsequent dose, or doses, of nembutal and chloral: pot. brom. grs. 25; chloral hydrate, grs. 25; tinct. opii η 7½; aq. chlorof. ad ξ 1.

There was no alteration in the ordinary management of the first or second stage of labour, except that after the administration of the nembutal the patients were not allowed out of bed. They were encouraged to sleep, but no precautions were taken to darken the room or ensure more than ordinary quiet. Further, the foetal heart was examined hourly and frequent blood-pressure records were made. Patients well under the sedative and sleeping quietly were frequently left alone for a few minutes at a time; mention will be made later of the restlessness sometimes met with, in which it was impossible to leave the patient at all.

THE PATIENT'S POINT OF VIEW

The matter was discussed with each patient 24-48 hours after delivery. All could remember being given some drug to drink, and whether or not there was any change in the pain after it. It is interesting to note that the same phrases occurred again and again in these women's description of their labours. 'I went to sleep at once and I didn't remember anything till I heard the baby cry.' 'All I remember was being given stuff to smell.' 'I felt things as though it was a dream, and there was no pain at all.' 'I was helped a lot.' 'It made the pain worse and the baby came at once.' There is a large clock in each labour ward, and one or two of the more intelligent women could remember the time they were 'given their drink' and the time when they woke up again. This was unusual.

Of these 100 cases, 62 were completely successful from the patient's point of view. The cases were classified in five groups as follows:—

- (a) *Very good*, 35. Complete or almost complete amnesia and complete analgesia.
- (b) *Good*, 27. Marked but incomplete amnesia and complete analgesia.
- (c) *Fair*, 21. No amnesia, but definite analgesia.

(d) *Poor*, 4. No amnesia, slight analgesia, quickly passing off.

(e) *Failures*, 13. Neither amnesia nor analgesia.

From these figures, therefore, in 62 cases the desired effect was obtained, in 21 the effect was very incomplete, and in 17 the drug was without effect.

THE ATTENDANT'S POINT OF VIEW

At University College Hospital women in labour are examined in the admission room. They are then transferred to the first-stage ward, which is capable of accommodating three women, and when in the second stage are transferred to a second-stage ward. The labour wards (second-stage wards) have only one bed. A normal labour is under the supervision of the labour ward sister only.

It was not found necessary to vary these arrangements with regard to patients under nembutal and chloral, except in the cases which were very restless. These were moved from the first-stage ward to the second-stage ward rather sooner than usual and not left alone. Those who responded well were left for a few minutes at a time. No case gave rise to particular anxiety. There was no fall in blood pressure or undue narcosis produced by the drugs. No case became maniacal. From the attendant's point of view the patients have been divided into four groups.

(a) *Easy to manage*, 61. These patients slept between their pains, and responded to instructions when required. They could be roused to be examined, but when left alone slept quietly. With the pains they were roused, and were rather more apt to wriggle than the usual patient without nembutal. They were not noisy, but there was a tendency to weeping and lack of control.

(b) *Fairly easy*, 12. These patients were drowsy between their pains, but were noisy with the pains, and could not be roused as easily to make use of the pains.

(c) *Difficult*, 17. The patients were noisy and restless, weeping and miserable even between the pains.

(d) *Very difficult*, 10. These cases were extremely noisy and restless. They required constant attention and would not respond to directions in any way.

The disposition of the patient apparently made a difference. In (a) 47 were placid, 14 nervous; (b) 6 were placid, 6 nervous; (c) 5 were placid, 12 nervous; (d) 0 were placid, 10 nervous. This statement is of course not absolute, as in the 'difficult' group there were 5 patients who were placid and quiet though distressed with the pains. After the administration of nembutal and chloral they became noisy and restless. It was found, however, to be a good working rule that placid patients would respond well, and the labour ward sisters, after some experience with the drug, could foretell fairly accurately which patients would be troublesome during the second stage. At this point it is interesting to note that the disposition of the patient has apparently a definite bearing on the success or otherwise of the drug from the patient's point of view. Of the 62 successful cases from the patient's side, 40 were placid in nature and 22 nervous, while in the 17 cases in which the drug was found to be without effect 4 were placid and 13 very nervous. Further, in 5 of these 13 cases, the nervousness was made worse by the initial dose of nembutal so that the repeat dose had to be withheld. Even though a patient became restless and unhappy after her first dose of nembutal and chloral it by no means followed that the amnesia would be incomplete. One or two of the worst cases of restlessness, which were exceedingly noisy throughout, had nearly complete amnesia. 'They tell me I made a noise, but I don't remember anything about it.' Hence it seems fair to argue that a repeat dose given to the restless patients would have produced a certain degree of success. It was, however, impossible to give this dose because of the fear that the patients would roll off the bed; further, they could not be induced to make use of their pains.

One patient was rather more than usually sleepy next day; the others were perfectly normal. They all

slept through the third stage. Chloroform or gas-and-oxygen was given for the deliveries in all cases except two, the average time of administration being about ten minutes, just for the actual predelivery pains, crowning, and birth of the head and shoulders. About 20-30 of chloroform was usually required. This amount was of course increased for forceps delivery. The number of perineal tears resulting was small. The temperature, pulse rate, and blood pressure of the patients after delivery were apparently not affected by the nembutal and chloral.

EFFECT ON THE PAINS

In 71 cases the strength and frequency of the pains were unaffected. Labour progressed normally and delivery took place within the expected time. In 9 cases there was considerable strengthening of the pains following the nembutal and chloral, and delivery took place with some rapidity. As this occasionally happens with patients who have had no preliminary sedative it seems doubtful if the strengthening should be regarded as a direct effect of the drug. O'Sullivan and Craner, in their series of 60 cases, had 3 in which a similar strengthening was observed.

In 20 cases labour was apparently lengthened. In 7 of the 20 the frequency of the pain was diminished, the intervals between pains lengthening from about three to five minutes, or four to six minutes. In 8 the strength was diminished. In 5 both strength and frequency were diminished. Fourteen of these 20 cases terminated in spontaneous deliveries, and the lengthening of the second stage gave rise to no anxiety. Six cases terminated in forceps deliveries. Forceps were applied for weakening pains and a lengthy second stage.

In this series of 100 cases there were 10 forceps deliveries. In 6, as stated above, forceps were applied for delayed second stage owing to weakening pains, but in 4 of the 6 the membranes ruptured very early, and it seems fair to assume that labour would have been long whether or not nembutal had been given. In the remaining 4 cases there was no weakening of the pains; in 1 of them there was some disproportion and the case was a trial labour, and in 3 the position was an unrotated occipito-posterior. The average for forceps deliveries at University College Hospital is about 9 per cent; this series, therefore, shows a slight increase. In spite of the prolonging of the labour 9 of these 20 patients had complete analgesia, 5 had fair but incomplete relief from the pain, 3 had very slight analgesia, and 3 had none at all.

EFFECT ON THE CHILD

In 79 of the 80 cases of unprotracted labour there was no anxiety with regard to the child. The babies all cried at once and were normal in every respect. In the remaining case the child was born in white asphyxia but was resuscitated fairly easily. In 16 of the 20 cases in which labour was prolonged the babies gave rise to no anxiety. In 3 of the 20 cases the following notes were made:—

Case 51.—Child slightly blue. Easily and quickly recovered. Forceps delivery under full chloroform.

Case 55.—Child slightly blue. Quickly recovered. Chloroform for delivery.

Case 99.—White asphyxia. Fairly easily recovered. Forceps delivery under full chloroform.

In one case there was a stillborn baby. Throughout labour, pains were strong but progress slow. Nembutal grs. 7½ and chloral hydrate grs. 44 were given in 15 hours, starting 21 hours before the birth of the child. The first repeat dose was given 16 hours before delivery, but before that the foetal heart could not be heard. Extract from the post-mortem report: 'Cause of death—asphyxia'. It seems questionable, therefore, if the nembutal had any bearing on the stillbirth.

CONCLUSIONS

From this analysis of 100 cases it seems fair to conclude that nembutal, given in combination with

chloral, is of undoubted value in labour. (1) It seemed to be of most use in placid or fairly placid women whose pains were strong and distressing; (2) it was most effective when given between 3 and 5 hours before delivery; and (3) when the patients had not been admitted more than 8-12 hours, so that labour was well established before the women had to be kept completely in bed; (4) on the other hand, it was found to be of very doubtful value in nervous or hysterical patients, both from the lack of analgesia resulting and the extreme restlessness induced.

Nembutal grs. 3 in capsules given by the mouth and followed by chloral hydrate grs. 22 as a syrup, grs. 11 to the drachm, were found to be perfectly safe. In no case, with the repeat dose (nembutal grs. 1½ and chloral hydrate grs. 22) in three hours, was there any suggestion of overdosing; indeed most of the 21 cases classed as 'fair' would probably have been successful as regards analgesia if the drug had been pushed.

Without the general anæsthetic for delivery there would not have been such complete amnesia in the 'very good' cases. Most people, however, agree that the worst pain is felt not when the child is actually being born, but when the head is descending through the pelvis. Therefore a considerable amount of relief could be obtained in ordinary cases without chloroform.

These results would probably be better in domiciliary midwifery, where one nurse stays with the patient all the time and where quiet and freedom from disturbance can be ensured.

Some Common Eye Diseases in Adults

By A. H. LEVY, F.R.C.S.

(Abstracted from the *Medical Press and Circular*, 11th October, 1933, New Series, Vol. CXXXVI, p. 334)

Ingrowing eyelashes.—Apart from the gross cases, the result of trachoma or of the more severe forms of blepharitis, eyelashes may occasionally deviate in direction from the normal and, bending backwards, impinge upon the eyeball and give rise to irritation, chronic conjunctivitis, or even keratitis. Occasionally a hair may grow from the caruncle and give rise to similar irritation. It usually suffices to remove the offending eyelash with a forceps, the succeeding lash generally growing in the normal direction. If not, the follicle had better be destroyed by electrolysis. The negative needle is inserted into the follicle, and a current of 3 to 5 m.a. passed for about one to two minutes.

CONJUNCTIVITIS

The affections of the conjunctiva are the commonest forms of eye trouble, and can be exceedingly troublesome. They may be divided into two main categories: physico-chemical reactions, and infections. Foreign bodies may irritate the conjunctiva by their mere presence, or they may also contain chemical irritants, as, for instance, aniline dyes. A bit of the lead of an indelible pencil can cause extensive sloughing, if allowed to remain in for any length of time. Certain organic substances act in the same way, as, for instance, certain pollens in the production of hay fever.

The infections of the conjunctiva are many and various, but for practical purposes can be divided into the acute and chronic forms. The commonest form of acute conjunctivitis is that due to the pneumococcus, and has been described in a previous article. A less common form is that caused by the Koch-Weeks bacillus (a very small Gram-negative bacillus). This may occur in epidemic form, but as such is rare in this country. Treatment should be continued for a long time, and consists of cold lotion, such as oxy-cyanide of mercury, 1 in 8,000, with occasional applications of 2 per cent silver nitrate. Argylol drops, 10 per cent, are also very useful. To prevent the lids sticking together any indifferent ointment smeared on

the edges of the lids at night suffices, but if the condition becomes chronic then the insertion into the conjunctival sac of 1 per cent or 2 per cent yellow oxide of mercury is very helpful.

Chronic conjunctivitis can be subdivided into many forms, but the most frequent is caused by the Gram-negative diplobacillus of Morax-Axenfeld. Characteristic of this type is the redness of the lids, frequently both conjunctival and skin surfaces, and limited more or less to the canthi. Patients complain of itchiness, the feeling of sand in the eye, and stickiness of the lids in the morning. Zinc sulphate is specific for this form of conjunctivitis, used as an eye lotion of the strength of one grain to the ounce, or as drops of double that strength. It is to be remembered that this form of conjunctivitis is very prone to recur, and therefore the treatment must be prolonged at least six to eight weeks.

LACHRYMAL APPARATUS

An increased flow of tears can only be caused by two conditions, hypersecretion of the gland or interference with the outflow passages. Hypersecretion of the gland practically always means some irritation of the eyeball—from a foreign body on the cornea or under the upper lid to an inflammation of the cornea or internal structures of the globe. The cause must be found and treated, whereupon the watering of the eye will cease. Interference with the outflow may be caused by the impossibility of tears entering the passage, or by some mechanical hindrance in the canaliculi, the tear sac, or the naso-lachrymal duct.

Under the first heading there is primarily malposition, especially of the lower lid. An eversion which carries the punctum away from the globe, and which if allowed to persist will lead to a definite ectropion. This condition is seen in flaccid lids, especially in elderly people, facial paralysis, cicatricial contraction, etc. An occasional cause of obstruction to the outflow of tears is the impaction of a cilium in the lower punctum.

If there be no interference with tears entering the passage, the obstruction must be more deeply seated, and may be of many different kinds and in various situations. The localization of such obstruction can be gauged by pressure over the tear sac. If there be regurgitation through the canaliculi into the conjunctival sac, then the obstruction must be below the point of pressure. If there be no regurgitation, then the site of the obstruction must be proximal to the point of pressure, i.e., along the canaliculus or at the point of entrance of the canaliculus into the sac. There may be a stricture from an old ulceration in the duct, or as the result of some periostitis. Passing a medium-sized lachrymal probe after a preliminary dilatation of the punctum will show the point of obstruction, and by dilating any stricture cure or relieve the condition. If the sac has been the seat of prolonged inflammation, then pockets full of pus and diverticula will have formed, and more serious surgical procedures must be undertaken.

CORNEA

Foreign bodies.—In searching for foreign bodies it is essential to have good illumination, with the light falling obliquely on the cornea, and a loupe through which to examine the cornea. It is well to instil cocaine first so as to eliminate the watering and the photophobia. In searching for a foreign body the upper lid should always be everted, as frequently foreign bodies get lodged in this position.

Superficial and deep keratitis.—There are many forms, some of which have been described in a previous article. In adults the commoner forms of keratitis are those associated with injuries and infections of the cornea directly, or extensions of inflammatory processes from the surrounding conjunctiva, as in trachomatous ulcers and pannus. And there is also that form which is associated with nerve lesions, as in peripheral neuritis, herpes febrilis, herpes zoster ophthalmicus and surgical interference with the Gasserian ganglion.

A common form which merits special notice is the hypopyon ulcer. This is a superficial ulceration of the cornea in which the anterior chamber becomes partially filled with sterile pus, and which clears up when the ulcer heals. The best treatment is to scrape the base of the ulcer with a small sharp spoon, and then with a finely-pointed match-stick to apply pure carbolic acid to this surface, being careful to allow the acid to penetrate underneath the overhanging edge of the ulcer, frequent douching with a mildly antiseptic lotion, and using an occluding bandage.

Herpes zoster ophthalmicus is always to be regarded as a serious affection. As long as the eruption is limited to the distribution of the supra-orbital nerve the treatment will be the usual one, but in addition it will be well to keep a close watch on the eyeball, and to instil atropine once or twice daily to minimize the effect of any cyclitis which may appear, and which will be mentioned later. If, however, the cornea should become the seat of an herpetic ulcer, the condition immediately becomes very serious. At the best the healing process will leave a scar which will almost certainly impair vision, and at the worst the ulcer will lead to perforation of the cornea and possibly destruction of the eyeball. It is to be noted that the cornea is only involved in those cases in which the area supplied by the nasal branch of the ophthalmic division of the fifth nerve shows the herpetic vesicles. The reason for this is that the ciliary ganglion from which the eye derives its sensory fibres is itself supplied by twigs from the nasal nerve as it passes across the orbit. The nasal nerve supplies the mucous membrane of the nose and the area of skin comprising the tip and alæ of the nose. Hence when these parts are involved the eye must receive special attention. The treatment must be directed to protecting the cornea as much as possible. An occlusive bandage, warm bathing and atropine, 1 per cent, with possibly rest in bed.

Beyond the direct involvement of the eye in the herpetic process, a deep-seated cyclitis is frequently seen in all forms of herpes of the ophthalmic division of the fifth nerve. This is characterized by tenderness over the ciliary region, redness, and usually many precipitates on the posterior surface of the cornea. As a rule this is a very resistant form of cyclitis, and requires prolonged treatment.

In all herpetic affections of the eyeball it must be remembered that the sensibility of the cornea is considerably reduced, so that the normal protective mechanism functions badly. Foreign bodies may remain on the cornea and give rise to ulcers, and there occurs superficial keratitis of a more or less intractable or recurrent nature. In addition there are active destructive processes analogous to those seen on the cornea after removal of the Gasserian ganglion, or its injection with alcohol for trigeminal neuralgia. All these types of disorder are best treated by complete occlusion of the eyeball, even to the extent of sewing the lids together. To do this it is necessary to raise the edges of the lids, and to place the sutures so that they do not come into contact with the cornea.

SCLEROTIC

Scleral tissue is analogous to the tissue of tendons, and the inflammations affecting it are similar; characteristically in scleritis there is local thickening and hyperæmia. This thickening may go on to the formation of a definite swelling, which practically never softens or breaks down, and may last for weeks or months and finally disappear. Recurrences are frequent, but as long as the changes are limited to the superficial layers (episcleritis) no great harm is done. It is only when the major part or whole thickness is involved that there is left a localized thinning of the sclerotic which may lead to local ectasias. The treatment consists of hot fomentations, and the application of one of two per cent yellow oxide of mercury ointment.

The general health should receive attention, and any septic focus treated.

IRITIS AND IRIDO-CYCLITIS

The whole uveal tract, iris, ciliary body and choroid, is a vascular structure partaking of the nature of a serious synovial membrane, and is subject to inflammations of the same type. It is rare to get an inflammation of one part only, although certain types tend to involve one or other part more intensely than the rest. It is difficult in any given case to be certain of the exact cause, but the principal things to remember are chronic gonorrhœa, septic foci in the teeth, tonsils, etc., and, after that, tuberculosis and syphilis. The symptoms of the commoner forms of iritis are ciliary injection, pain, and the formation of synechiæ. The pain is due to the swelling and constant movement of the iris. The ciliary injection is a reddish-blue area just outside the corneal limbus, and is due to engorgement of the ciliary body. The synechiæ are the result of the plastic exudate from the inflamed iris which causes it to adhere to the anterior capsule of the lens. In the treatment atropine is the sheet anchor. It stops all iris movements and thus quickly relieves the pain, and it dilates the pupil so that its margin is no longer in contact with the lens capsule, and thus obviates the formation of synechiæ. Hot fomentations are a powerful adjuvant, and beyond this the treatment of the underlying cause must be undertaken.

GLAUCOMA

Any eye in which the intraocular tension is raised above the normal is termed glaucomatous. There are the primary cases in which the ætiology is obscure, and the secondary forms in which it is due to alteration in the nature or some interference with the normal outflow of the aqueous fluid. If the rise of tension be acute then there occurs pain, which may be exceedingly severe, congestion and dilatation of the pupil. If the rise be slow, then there will be no pain, but only a slowly progressive loss of field and, later, diminution of visual acuity. The treatment in the acute forms is operation; in the chronic forms miotics, such as eserine, or operation.

The more deeply seated inflammations of the ciliary body (cyclitis) and choroid are, generally speaking, due to the same causes as iritis, and the treatment should be along the same lines. In this connection it is necessary to mention keratitis punctata. This is a deposit of fine particles on the posterior surface of the cornea, and is symptomatic of cyclitis. The inflammatory exudate from the ciliary body is carried by the aqueous into the anterior chamber, and in the course of the ordinary circulation of the aqueous fluid comes into contact with the cornea and, being sticky, adheres to it. In all inflammations of the interior of the eye careful search should be made for these deposits, as their presence helps greatly in determining the seat of the inflammatory change.

Iritis is occasionally confused with glaucoma, acute or chronic. The differentiation of these two conditions is of fundamental importance, since the treatment of glaucoma with mydriatics will inevitably damage the eye, and the treatment of iritis with miotics will increase the pain and lead to the formation of dense synechiæ. The differentiation is all the more difficult inasmuch as the tension of the eye may be raised in iritis by the increase of the quantity of fluid in the eye and its albuminous nature. The main points are that in iritis the pupil tends to be contracted, while in glaucoma it tends to be dilated. The field of vision will be contracted in glaucoma particularly on the nasal side. The cornea in glaucoma tends to be hazy and the aqueous clear, while in iritis the cornea may be clear, but the aqueous will be muddy. In cases of doubt the instillation first of cocaine and later of homatropin will help to clear up the diagnosis.

Reviews

AN OUTLINE OF IMMUNITY.—By W. W. C. Topley, M.A., M.D., F.R.C.P., F.R.S. 1933. Edward Arnold and Company, London. Pp. vii plus 415. Price, 18s.

To those who share the opinion of the reviewer, that Topley and Wilson's *Principles of Bacteriology and Immunity* is the best book on the subject that has been written, the appearance of this new book on immunity will be noted with agreeable anticipation. The basis of the present volume is, of course, the sections on immunity in the earlier book, but there has been considerable re-arrangement, the sections have been re-written, much has been added, and—we are told in the preface—there have been a few omissions.

There is a great deal to be said against the disruption of medical science into a number of '-ologies', but there does not seem to be any alternative; we must accept the necessity for this division and make the best of it by the encouragement of good liaison work. Immunology was not particularly well mated to bacteriology, and it is certainly more closely associated with clinical medicine than is the latter; possibly therefore this divorce from bacteriology will lead to a closer association with clinical medicine.

The first meaning of the word 'immunity' was freedom from service; then it was applied in a legal sense to mean freedom from certain taxes; and finally, about fifty years ago, it was applied to the state of insusceptibility to certain infectious diseases, particularly when this was brought about by inoculation, under the misapprehension that this was absolute. This is precisely what immunity, as we understand it now, does not mean. Complete insusceptibility, as Professor Topley says, would do away with the relationship between host and parasite, and our interest in the matter would be finished; but as long as it is understood that the word means the total reaction produced by the association of the host and parasite, it will serve its purpose. A complete appreciation of this fact will carry a student a very long way towards an understanding of the whole subject, and far beyond the state of knowledge in which the earlier textbooks have left his predecessors.

An early chapter is headed 'The measurement of immunity and reaction in the living animal'. Although it fits very well in its place in the book, this chapter provides very suitable reading for the medical research worker. In the section on the assessment of significance the author has broken all the canons of writers on statistical subjects and has treated the problem in such a way that a reader of mediocre intelligence (e.g., the reviewer) can understand it.

One cannot say that the subject is dealt with systematically because it is impossible to say what should be the natural sequence, and, if one chapter does not lead on to the next, at least the order in which they have been placed is a logical one. Everything is there; that is to say, everything to do with immunity in bacterial and virus diseases; the subject of immunity in protozoal diseases has not been touched upon except in a very general way.

In a book of this nature it would be impossible to avoid controversial subjects, but the author discusses them without heat, even when expressing his opinion on Besredka's theories regarding local immunity, and without apparently displaying any marked prejudice; he naturally expresses his own opinion, which, in view of his reputation, must carry a great deal of weight.

It is hard to pick out any chapters for special mention, but one, the chapter on herd immunity and herd infection, cannot be passed over; the author displays a very characteristic attitude when he reviews the evidence for the assumption which nearly all epidemiologists make, that the virulence of an organism at

different stages of an epidemic varies; he concludes that none of it will bear close examination. Other popular assumptions are robbed of much of their dazzle after they have been filtered by his cold reasoning; for example, one does not feel nearly so confident that the preventive inoculation really reduced the pneumonia in the South African mines, after reading the section on this subject, as one did before.

Each chapter is concluded with a very valuable summary, and a number, but not an overwhelming number, of references.

One can safely say that this is the most important book of its kind that has been written for a number of years. The author claims that it is written for the young student, and admittedly it is written in such a way that he can understand it, but it is also a book for the post-graduate student, the teacher, and the research worker; to the last-named we can particularly recommend it.

L. E. N.

THE PRACTITIONERS' LIBRARY OF MEDICINE AND SURGERY. Volume IV. (Non-traumatic Surgery). 1933. D. Appleton and Company, New York and London. Pp. xlviii plus 1146. Illustrated. Obtainable from Messrs. Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 37-8 per volume

THIS is the fourth volume of that very ambitious, and so far very successful, encyclopædia, the *Practitioners' Library*. An original, but very satisfactory, division of the subject of surgery has been made; this volume is entitled 'Non-traumatic Surgery'. There is much to be said for this division; of course, many non-traumatic conditions are complicated by trauma, but allowance has been made for this and where primarily non-traumatic conditions are likely to be complicated by trauma the point is discussed; inversely, one assumes, in the volume on traumatic surgery, non-traumatic complications, which in this case are often more important than the primary injury, will be discussed. This overlapping cannot be used as an argument against this division of the subject, any more than could the frequent medical complication of a surgical case for this centuries-old division of medical science.

There are twenty-two chapters, with a few exceptions each contributed by a different writer. There is a short chapter on neoplasms, otherwise the division is regional, the breast, the neck, the thyroid gland, etc., or by 'systems', the urinary system, bones and joints, etc.

This volume is well illustrated throughout; many of the surgical procedures are shown step by step, and in a number of instances the diagnostic features of deformities and diseased conditions are so well demonstrated by photographs as to make the reading of the text almost unnecessary.

We have one criticism in connection with the illustrations. Why in taking a photograph for reproduction in a surgical book is it necessary to cover the genitalia of even young children and thereby detract very considerably from the value of the illustration? In one instance in this book a side view of a child with congenital double dislocation of the hip is entirely ruined by bits of material plastered all over the buttock.

The book is quite up to the high standard set by the earlier volumes in this series. It is a high-priced book, but it is very good value for the money. Messrs. Butterworth, the agents in India, have asked us to mention that the complete set may be obtained through them on the instalment system.

COMBINED TEXTBOOK OF OBSTETRICS AND GYNÆCOLOGY FOR STUDENTS AND MEDICAL PRACTITIONERS.—By J. M. Munro-Kerr, M.D., F.R.F.P. & S. (Glas.), F.C.O.G., J. H. Fergusson, M.D., LL.D., F.R.C.S. (Edin.), F.R.C.P. (Edin.), F.C.O.G., F.R.S. (Edin.), J. Young, D.S.O., M.D., F.R.C.S. (Edin.), F.C.O.G., and J. Hendry, M.B.E., M.A., B.Sc., M.B., F.R.F.P. & S. (Glas.), F.C.O.G. Second Edition. 1933. E. and S. Livingstone, Edinburgh. Pp. xii plus 1100, with 497 illustrations, and additional x-ray plates. Obtainable from Messrs. Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 26-4

THIS admirable book provides the student or medical practitioner with all that he need know of obstetrics and gynecology, in a volume of moderate size. It has been brought up to date and gives in admirably clear fashion all the latest additions to our knowledge of these subjects. The book is very well written throughout and is a model of clearness and compression. The illustrations are abundant and excellent.

The first 670 pages deal with obstetrics. Then there is a very interesting and educative chapter on puerperal mortality. The remaining 400 pages deal with gynecology. This section opens with a connecting chapter between obstetrics and gynecology. In this it is said that 'there is no greater opportunity for the exercise of preventive treatment in the whole realm of medicine that is afforded in midwifery practice'. The book ends with a short chapter on radiology in obstetrics and gynecology written by Dr. Duncan White. The obstetrical part contains an excellent chapter on the care of the newly-born infant, by Dr. Charles McNeil. This chapter deals with the first month of life much more fully than is usually done in manuals of midwifery, and it should prove of the greatest service to the doctor in charge of such infants. A particularly interesting chapter is that on the physiology of pregnancy where all the changes in the maternal organism are lucidly described. The author states that 'eclampsia is rare in warm climates' this they attribute both to the heat and largely vegetarian diet. That eclampsia is rare in warm climates is certainly not true, in Bengal or Madras where it is extremely common although the people are vegetarians. It is rare in the Punjab where the people are meat eaters. The deciding factor would appear to be neither temperature nor diet, but humidity.

J. M.

DISEASES OF INFANTS AND CHILDREN.—By J. P. C. Griffith, M.D., Ph.D., and A. G. Mitchell, M.D. 1933. W. B. Saunders and Company, Philadelphia and London. Pp. xvi plus 1155, with 280 illustrations. Price, 50s.

THE authors in attempting to produce a textbook which will appeal to the undergraduate and the pædiatric expert alike, have undertaken a task extremely difficult of successful accomplishment no matter how experienced the authors may be. The student looks for dogmatic teaching, while the expert looks for the latest theories and possible lines of research. Both are liable to be disappointed in the present volume. The student will find the innumerable references to names in the body of the text irksome, and the teaching not sufficiently dogmatic, while the pædiatrist will look in vain for any reference to the work of Dr. Helen Mackay on nutritional anæmias in children, or for an account of 'infantile liver' so frequently given as a cause of deaths in children in Calcutta.

The section dealing with the care and nutrition of the normal infant is comprehensive, though test-feeding, an important demonstration to doctor and parent alike of the adequacy or otherwise of the amount of milk ingested, is conspicuously absent and the proprietary foods mentioned being all of American manufacture are neither well known nor readily obtainable in India.

The major part of the book deals with disease; disease in the newborn, infectious disease, a section on

nutritional and miscellaneous disease which includes rheumatism, and sections dealing with disease in the various systems and special senses in turn. The balance is on the whole well preserved and the teaching up to date, though the compression inevitable in a one volume book has necessitated several minor, though important, omissions, as, for example, of the part played by the swimming bath in the spread of molluscum contagiosum. Under functional nervous disease the term 'eclampsia' is applied to convulsive attacks, resembling tetany, that occur in early life. The American spelling of 'edema' and 'fetus' is used throughout. Despite the sound teaching, the excellence of several of the illustrations, and the successful coloured plates, depicting vaccination, the Mantoux test and different stools in infants, the book has no outstanding quality which will cause it to replace in popularity any one of the excellent textbooks on the subject published by English authors.

J. M. O.

PEDIATRICS.—By Henry Dwight Chapin, M.A. & M.D., and Lawrence T. Royster, M.D. Seventh Edition. 1933. Baillière, Tindall and Cox, London. Pp. xvi plus 775, with 149 figures. Price, 35s.

FOURTH editions of this American book were entitled *Diseases of Infants and Children* but with this edition the name has been changed to *Pediatrics*. The authors define pediatrics as 'the study of normal growth and development both physical and mental, the phenomena of metabolism and nutrition which promote normality and the prevention of pathological states', while it also retains its original function of the study and treatment of disease in children. It will be seen, therefore, that the book covers a very wide field. The first section is devoted to growth and development, beginning with foetal development and antenatal influences; the next sections to the newly-born infant, the sick child and infant feeding. Dr. Royster recommends lactic acid whole milk as the best artificial food for infants. The various food and milk preparations described in this section are American brands and perhaps are not so well known or so easily obtainable in India as the corresponding European preparations. Tables of foods recommended for young children by the American Child Health Association are given. It is rather surprising to find bacon included in the breakfast menu from 12 months onwards. The remaining sections of the book deal with the diseases of childhood, including the exanthemata, commoner surgical diseases, and diseases of the eye, ear and skin. The scheme of the book is very ambitious and the effort to make one volume deal with so much has not been altogether successful. This is particularly so in the first section where the subject is dealt with in so general a manner as not to be of much practical use. However, the fact that the first edition appeared in 1909 and that this is the seventh denotes the general usefulness and soundness of this volume.

J. M.

A HANDBOOK OF PSYCHIATRY.—By J. H. Ewen, M.R.C.P. (Edin.), D.P.M. 1933. Baillière, Tindall and Cox, London. Pp. viii plus 267. Price, 12s. 6d.

THIS book will be found of great service to those for whom it is primarily intended, namely, medical students or medical practitioners desirous of obtaining a diploma in psychological medicine. In other words, it is an excellent cram book. The author is well advised to bring to the notice of his readers that our present knowledge of mental disorders precludes the presentation of an adequate classification of them. The author's chapter on the aetiology of mental disorder is excellent and repays careful study. The only outstanding defect, but one more or less inevitable in books of this description, is an excessive compression

voluminous textbooks on the subject has been condensed in it in such a way as to facilitate quick revision.

N. P.

ANATOMY, PART IV (ABDOMEN), CATECHISM SERIES.—By C. R. Whittaker, F.R.C.S.E., F.R.S.E. Fourth Edition (Revised and Enlarged). E. and S. Livingstone, Edinburgh. Pp. 84. Price, 1s. 6d.

This book of the Catechism Series deals with the abdomen in the form of questions and answers. The first 11 pages are devoted to the male and female perineum. The next 11 pages contain the description of the abdominal wall, the inguinal region being specially dealt with on account of its surgical importance. In the description of the subcutaneous inguinal ring the crura have been misplaced. In the subsequent pages the abdominal cavity with the contained viscera, vessels, and nerves have been described. The relations of the organs and important vessels have been nicely put in a tabulated form suitable for quick revision. Similarly the branches and tributaries of the vessels have been enumerated in tabulated form. The new nomenclature has been chiefly adopted throughout. This small book will be specially appreciated by students preparing for their examination in anatomy as it will facilitate quick revision of the subject and help in writing up answers in an appropriate and concise form.

N. P.

A TEXTBOOK OF BOTANY.—By James Small, D.Sc., Ph.C., F.L.S., F.R.S.E. Third Edition. 1933. J. and A. Churchill, London. Pp. x plus 717, with over 1,350 illustrations. Price, 21s.

This profusely illustrated and well-got-up volume will be useful to general, as well as to medical and

agricultural, students as a textbook. It has been written in an easy and readable style, and the numerous illustrations it contains will enable students to get an insight into the subject with ease and accuracy. The chapters on fruit and seed dispersal, germination, and pollination are dealt with in a very interesting and educative manner. In the section dealing with physiology, the most difficult subjects, such as those of osmosis, ecology, plant enzymes, heredity, carbon assimilation and protein synthesis, are treated in such a lucid and clear style as would only be expected from a very experienced teacher. The references at the end of each chapter will be useful to those who wish to go into further detail regarding these subjects. The appendices, in which the diagnostic characters of important medicinal plants and the life history of the special types of the lower vegetable kingdom are described, will be useful to students whereby to learn important points in connection with the description of the plants for purposes of identification, and for studying the life history of the lower organisms of the vegetable kingdom.

Abstracts from Reports

ABSTRACTED FROM THE ANNUAL REPORT OF THE CHEMICAL EXAMINER TO THE GOVERNMENT OF MADRAS FOR THE YEAR 1932

ANALYTICAL NOTES

Madur.—A common and poisonous weed that grows all over India is madar (*Calotropis gigantea*) a plant with pink or white flowers and fat fleshy leaves which on crushing exude a sticky white juice. This juice is not uncommonly used both as a poison by the mouth and as an abortifacient introduced into the uterus on a small stick. In addition to the tests for it described in my report for 1931, we have found that an alcoholic extract of the juice saponified with caustic potash gave, on extraction with petroleum ether, a fairly abundant white crystalline substance freely soluble in ether and chloroform. This substance may also be extracted by evaporating off the alcohol from the saponified alcoholic solution and extracting with ordinary ether. It yields with sulphuric acid a crimson colour. Even in the presence of fats as in the case of visceral matters this substance can be easily extracted in cases of madar poisoning. Further work on this substance is held up at present owing to the pressure of routine work.

Oduvan leaves.—The acid ethereal extract from the leaves gives a green colour with strong hydrochloric acid, a purple colour with strong sulphuric acid and causes paralysis and death when injected under the skin of a frog. In the viscera, however, the green colour with hydrochloric acid often cannot be obtained though the reaction with sulphuric acid and the physiological action on frogs are obtained. A microscopic examination of the oduvan leaf shows the following

characteristics which might enable one to identify the leaf:—

(1) An upper epidermis of polygonal cells with no stomata.

(2) A single layer of palisade cells.

(3) A spongy mesophyll with large prismatic crystals of calcium oxalate in abundance along the course of the vessels on either side of them.

(4) A lower epidermis of wavy-walled cells with numerous stomata. The stomata are surrounded by two cells each of which is parallel to the osticle.

The root of this plant is also poisonous.

Oleander.—Yellow oleander is one of the most commonly used poisons in Madras. The red variety is much less frequently used. Both oleanders give acid ethereal extracts fatal to frogs and which produce a characteristic deep violet colour with strong sulphuric acid after the lapse of several hours. In the case of yellow oleander a green colour is obtained on boiling the fresh kernels with sulphuric acid, but in the case of viscera this colour is not obtained after digestion in the stomach. Dr. Rajagopal Nayudu has been investigating the poisonous constituents of oleander for some years as time can be found, and the following results are of interest:—

Dried yellow oleander kernels were pressed to squeeze out most of the oil, and the powdered cake was extracted in a Soxhlet, using a mixture of chloroform and ether, so adjusted that the extraction occurred in the presence of one volume of chloroform to two of ether in the Soxhlet. The ether chloroform extract was evaporated to dryness and washed with petroleum ether to remove the remaining oil. This was named *Extract A*. The kernels were next extracted with absolute alcohol. After evaporating a portion of the

alcohol from the alcoholic extract ether was added to it, when a white precipitate appeared in abundance. This was filtered, again dissolved in a small quantity of alcohol and re-precipitated by ether. The precipitate was dried. This was called *Extract B*.

Extract A was found to be nitrogen free and on combustion analysis gave 7.1 per cent hydrogen, 58.1 per cent carbon, and 34.5 per cent of oxygen by difference. Dragendorff's analysis of thevetin gave the following results:—hydrogen 7.53 per cent, carbon 58.06 per cent and oxygen 34.11. So this extract is probably thevetin. *Extract A* melts at 178°C. with decomposition. It is very soluble in chloroform and sparingly so in water and in ether. On boiling with hydrochloric acid this extract does not give a blue colour. It gives a cherry-red colour turning to violet with concentrated sulphuric acid. When a dilute solution is painted on a frog's heart, at first the contractions are stimulated, then irregularity follows with contractions of the auricle only for some time, the ventricle being in tonic contraction. Then the ventricle contracts a few times, and then the auricle alone continues. The rate diminishes and the heart stops in systole. Injected into the dorsal lymph sac of frogs it produces convulsions and death.

Extract B is freely soluble in water and in alcohol, but insoluble in ether and chloroform. On boiling with dilute hydrochloric acid it gives a deep blue colour. The aqueous solution has a tendency to froth on shaking. Even after purification the sample does not give a definite melting point as it appears to decompose at about 135°C. It is, however, very poisonous, 0.2 milligram killing with paralysis a frog weighing about half an ounce. A dilute solution painted on the exposed heart of a frog gives rise to tonic spasm of the ventricle, the auricle only working. Finally, the heart stops in systole. Ten milligrams injected hypodermically killed a cat weighing 22 ounces in 20 minutes. The symptoms noted were vomiting, paralysis, and asphyxial spasms prior to death. An examination of the toxicity of *Extract B* on animals gave a curious result. With white rats it was comparatively non-toxic. Doses up to 67 milligrams per kilogram of body weight (10 milligrams for a 150 gram rat) produced no symptoms at all. On guinea-pigs on the other hand a much smaller dose was fatal—the minimum lethal dose being about 10 milligrams per kilo. of body weight. The symptoms in guinea-pigs were, (1) profuse diuresis, (2) convulsions, (3) paralysis, and (4) death, appearing in this order. With sublethal doses only the first one, two or three of these symptoms occurred and recovery began after one or two hours and was complete by the next day. It is hoped to continue the investigations on this extract when the rush of routine work permits.

CASES OF INTEREST

Eucalyptus oil.—There were two cases of suspected eucalyptus oil poisoning. In one of these cases a ticket collector and a girl with whom he was living drank about an ounce each of eucalyptus oil. They had vomitings and purgings. The stationmaster getting alarmed at their symptoms removed them to the local hospital. The purgings and vomitings were sent to this laboratory for analysis, and eucalyptus oil was detected in them. At the trial the accused stated that they drank the oil with a view to frightening others, and not to committing suicide. The medical officer who treated the cases testified that eucalyptus oil was not included in the list of poisons and was not ordinarily likely to cause death of the two persons even if they had not been treated. On this evidence the magistrate acquitted the accused. I am not sure that the doctor was quite correct in his opinion that eucalyptus oil is non-poisonous, though his opinion is the generally accepted one. In several cases in England a fairly small quantity has produced serious narcotic symptoms and I am inclined to consider that the comparative harmlessness of the eucalyptus oil as ordinarily bought

in the hazaar is due to its heavy adulteration with other oil—probably groundnut oil.

Aconitine.—There was a curious case of aconite poisoning in which a woman, at the instigation of her paramour, is alleged to have administered a potion to her husband, believing that it would have the effect of rendering him complaisant to her irregularities of conduct. The potion was given in clintney, but it is stated that the husband noticed a bitter taste in the clintney and threw it to the fowls. The taste of aconite is not markedly bitter and one would have thought in clintney its taste would have been completely masked till enough had been eaten to cause death. In this case five fowls are said to have eaten the discarded clintney and all of them to have died. The viscera of the fowls were sent to us and we found aconite in them. At the trial owing to many discrepancies in the prosecution evidence the accused was discharged.

Betel.—Cases of poisoning by chewing pan supari are reported from time to time though these are not generally fatal. The substance chewed consists of betel leaves wrapped round areca-nut and slaked lime. Which of the three constituents is the occasionally poisonous one is not certain. In a case sent here during the year under report a man aged about 30 after chewing a roll of betel leaves began to sweat profusely and suffered from vomiting and diarrhoea. In this case he did not recover, but his symptoms rapidly got worse and he went into convulsions, became unconscious and died within an hour. As usual in such cases we did not detect any poison in the viscera. Mr. T. R. Subrahmanya Ayyar, the Second Assistant Chemical Examiner, is investigating the alkaloids of areca-nut with a view to discovering which of them may give rise to these symptoms.

ABSTRACT FROM THE MUNICIPALITY OF SINGAPORE, HEALTH DEPARTMENT. ANNUAL REPORT FOR 1932

DR. HUNTER's reports are always interesting. They are always reasonably up to date, and not too long; he goes straight to the interesting matter and makes his points clear. In the present report, the first thing that is brought to our notice is the low death rate; 20.31 per 1,000 compared with 25.20 in 1931 and 27.73 in 1930. The peninsula of Malay, of which Singapore is the chief town, has during the last two years been more badly hit by economic depression than possibly any other country. The two staple industries, rubber and tin, have very nearly disappeared temporarily. Crowds of coolies and labourers have been paid off. Singapore of course has suffered greatly by these happenings and, moreover, the lame and the halt and destitute have drifted, as they always do in depressed times, to the metropolis.

Dr. Hunter reviews the situation. In the first place he comments on the complete absence of cholera, plague and smallpox (save for 8 cases) in Singapore during the year. He does not explain this extraordinary fact. He deals next with the criticism that his death rate is low as it is based on too high a population. It will be remembered that last year he discovered that 19,500 children had been missed in the census, and he added these to his population figure. The census officer naturally repudiates this assertion and states, according to Dr. Hunter, that the children were not missed but were carried forward into subsequent age groups. Dr. Hunter is not satisfied with this argument and still thinks that the children were missed at the census. Then there is an argument that the lower number of deaths is due to a smaller population, owing to wholesale emigration by Chinese and their families. One would have thought that there would have been more or less precise information on this point, but apparently there is not. From market and other returns, Dr. Hunter finds no evidence of diminished food supplies such as would have been expected, by a big

reduction of the Chinese population, and though the better class houses are less tenanted, there is gross over-crowding in the poor districts. So Dr. Hunter sticks to his guns and his low death rate (justifiably we think). He states that Singapore by its situation, its climate and its amenities *should* have a low death rate, and that in this year, 1932, Singapore was almost free from the usual influx of sick and destitute (this having exhausted itself in 1930 and 1931 owing to the shutting down of labour in the country to skeleton crews only). In 1932 therefore the city was free to show its real comparatively low death rate. Analysing the low death rate still further, Dr. Hunter asks the question whether the lowered death rate is simply due to the above fact, or to any real improvement in the sanitary and other conditions in the city during the year. The saving of life, compared with 1931, occurs in a varied group of diseases, headed by respiratory diseases and infantile convulsions followed by beriberi, which shows 180 fewer deaths than in 1931. The reduction in infantile convulsions led to a record low infantile mortality rate of 180.2 and Dr. Hunter pays a special tribute to the Maternity and Child Welfare work which is organized and run on sound and energetic lines and which he states is now undoubtedly exercising a very distinct effect on the reduction of infant mortality. It is still a high figure and an interesting investigation was and is being still carried out to find out some of the definite causes of the high figure.

Congenital syphilis and inanition due to maternal syphilis appears to be an unsuspected cause of many infant deaths and strenuous efforts are to be made to tackle this difficult question. The confidence of mothers is rapidly being gained and the welfare work amongst mothers and children is now on a very good footing and is yielding very definite results in saving of mother and child life and in improving the conditions and methods of life.

Dr. Hunter suggests another reason for the drop in the death rate—one put forward by Dr. Heiser who states that he has noticed that when chlorination of a large water supply has been instituted (whether the water previously was of a high bacteriological quality or not), there has followed subsequently a drop in the general death rates. Chlorination of the Singapore water supply has been instituted within the last year or two and Dr. Hunter wonders whether the phenomenon described by Dr. Heiser has anything to do with the lowered death rate. He does not commit himself but thinks the situation may be investigated further from this point of view.

Dr. Hunter's work on malaria is well known and his conclusion is that barring a few 'ludlowi' breeding areas in the low-lying parts of the town, Singapore is practically free from anophelines. The 'ludlowi' question is still with them—the reclaiming of a large 'ludlowi' breeding ground, the Kallang Basin, has been temporarily shelved on account of financial stringency. *A. ludlowi* is a funny insect however—at the present time its malaria-carrying propensities in Singapore seem to be in abeyance. Only an occasional case of malaria was reported from the districts in which it breeds and at no time were there any signs of an epidemic. Its present activities in Bengal are in distinct contrast to its behaviour in Singapore. Dr. Hunter's view is that in outbreaks of malaria associated with this mosquito the phenomenon seems in some way to be associated with some change in or disturbance of its breeding ground. This was the view taken by some when consideration of the 'ludlowi's' activities near Calcutta was commenced, but investigations did not seem to yield much information in this direction.

The report contains interesting reports of the work of the municipal laboratories and other departments. The examination of sludge from the Imhoff tanks shows that living hookworm larvae can be isolated from the

sludge after 88 days' life in the latrine; and the development into infective sheathed larvae could be followed from day to day. Hirst in Colombo found that ground in which septic tank sludge was buried was infective for at least 3 years. In Singapore the sludge was treated to 135°F. for 40 minutes to kill hookworm larvae; it was found however that round-worm eggs still continued to develop and the sludge is now raised to a temperature of 150°F. for 40 minutes.

ABSTRACT OF THE ADMINISTRATION REPORT OF THE DIRECTOR OF MEDICAL AND SANITARY SERVICES, CEYLON, 1932

THIS is a very comprehensive report of the activities of the Medical and Sanitary Services. The salient points are a little difficult to extract. Malaria seems a universal problem in the island, and plague seems to have established itself to some degree. Hirst's work on the entrance of plague into Colombo and its spread by exportation of *X. cheopis* to other parts of the island is well known. In 1932 there was more plague in Colombo than in any other seaport in the world. When plague appears powers are taken under a special ordinance to declare certain streets and buildings as 'diseased localities'. People and goods are prevented from getting in and out of such a locality. Evacuation of the people is then carried out and a rat-flea campaign instituted. The goods are then evacuated. Guinea-pigs are finally used as tests for absence or presence of fleas.

There was no cholera in the island during the year. About 800 deaths from enteric were registered, but many more were suspected. The birth rate was 37 and death rate 20.5 per 1,000; the infantile mortality 162. Yaws is endemic and over 23,000 cases were treated. The number is steadily decreasing annually. Treatment for yaws is given throughout the island by 'Itinerating Medical Officers' of whom there are now four.

Antimalarial measures are on the usual lines. The antihookworm campaign continues. A special dispenser for the work is known as 'Anky'. Mass treatment is carried out by health units. The numbers of treated are given, but the opinion is expressed that after so many years of campaign work, the results are not very encouraging. Only one-fifth of the population is receiving treatment and the other four-fifths continue the work of dissemination. An account is given of the large amount of work done in Government hospitals and dispensaries. The report bears testimony to good organization, administration and executive work over very wide fields.

ABSTRACT OF THE MUNICIPAL AND SANITARY REPORT ON HONG KONG, 1932. BY DR. A. R. WELLINGTON, DIRECTOR OF MEDICAL AND SANITARY SERVICES

IN our notice of this Annual Report for 1931 we commented on the peculiar sanitary and medical administration in the Island of Hong Kong which not only *must* make work difficult, but renders advance in certain directions almost impossible.

The Legislative Council itself performs the duties of a Municipal Council and the colonial heads of departments perform the duties which in a municipality would be performed by municipal heads of departments. Perhaps this is not surprising considering the fact that Hong Kong really consists of two towns—Victoria and Kowloon—the rest of the island being negligible and hardly inhabited.

The Director of Medical and Sanitary Services is the official adviser on all medical and sanitary matters. The sanitary department is distinct and independent of the director and has at its head a layman of the cadet service. It has attached to it, medical officers of health seconded from the medical department.

The present machinery for the promotion of the public health is complex. Organization of energy both for the cure and prevention of disease is divided among

a number of units which operate more or less independently of each other. Proposals have been submitted for the reorganization of the medical and sanitary services by which these anomalies will be remedied. Progress in this seems to be slow.

Sanitary conditions in the towns of Victoria and Kowloon are determined largely by their geographical features. Victoria is built on a narrow belt of shore land on the north side of the island. There is practically no room for expansion, and high narrow houses which are densely populated are a feature of the working class areas. There are in this part 1,000 persons per acre. Year by year the population has increased, immigration being accelerated by unrest in China. Houses and rooms have been divided and subdivided into permanent cubicles, with little or no room for kitchens, and latrine accommodation is often limited to pail closets on the roofs of buildings.

Tuberculosis is naturally widespread and in 1932 provided a death rate of 252 per 1,000. This is much below the real figure, as those afflicted with the disease and unable to work and earn a living go back to the Chinese mainland to die in their own villages. The problem is a difficult one and the housing problem seems almost insoluble. The town of Kowloon has been built more recently and has been laid out on definite lines. It is rapidly growing and will soon rival Victoria in population. Hong Kong suffered from cholera in the pandemic of cholera in China but, as the report says, the small epidemic in Hong Kong resulting in 241 deaths, might have been much more severe. There was also an epidemic of smallpox, with 212 deaths. Chinese custom does not allow of vaccination till the propitious time of the second birthday. Hence there is a very large number of unprotected infants. For the last 3 years there has been no case of plague. The disease has disappeared from Hong Kong and the same may be said of South China. The rat population is much the same as it was and, so far as is known, there is no change in the quantity or quality in the flea population. As the report says, in spite of the continuous campaign against rats, owing to the rapidity with which they multiply and the ease with which they enter and leave the colony, there still is and probably always will be a sufficiency of rats and

rat fleas in the colony to light up and maintain an epidemic 'if the Gods so will it'. We trust the 1894 story will not be repeated.

There was a sharp outbreak of cerebro-spinal fever. It would appear that the meningococcus has taken on a decided virulence in the East and Far East during the last 2 or 3 years. (In 1932 and 1933 there have been distinctly severe, though localized, outbreaks in India, in places as far apart as Calcutta and Lahore.)

Enteric fever, as one would expect, is fairly common though the spread seems to be mainly from cases and to some extent from carriers, but is never milk- or water-borne.

The department of health and medicine has many activities, and school hygiene and maternity and child welfare are good going concerns. There are many excellent hospitals, government and non-official. Voluntary effort is playing a large part in the education of the Chinese manners in health and social work, and hopeful progress is being made.

The Government bacteriological institute bemoans its isolated position and the overloading with routine work, which prevents several of the colony's problems receiving the attention they should.

Nevertheless, some interesting work has been done. In the epidemic of cerebro-spinal meningitis, the isolated organisms have been typed, and examinations of the total protein present in the cerebro-spinal fluid carried out by McNaught's method.

Type III was most numerous—71 per cent, type I coming next—22 per cent, 22 per cent being indefinite, and 4.4 per cent inagglutinable by any of the type sera.

Malaria seems fairly common, *Anopheles minimus* and *jeyporiensis* being the carriers. They breed in collections of seepage water near the hill side. A great deal has been done to free the town of malaria by large drainage schemes.

The analysts department reports a great deal of interesting chemico-legal and other examinations. Scarcely of poisoning of wells revealed a bit of carbolic soap and some clay and starch as the offending agents. There is still no Food and Drugs Act in the Colony.

We look forward to the next annual report principally to see what progress will be made in the sanitary administration of the Colony.

Correspondence

THE THERAPEUTICS OF MALARIA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—With reference to the recently-published report of the Health Organization of the League of Nations regarding the therapeutics of malaria, it would appear that this disease must react differently to treatment in various parts of the world.

I agree that the 'cinchona febrifuge' now obtainable is practically valueless, but can see no object in trying to devise a new cinchona preparation, when quinine is far more efficacious, and should be much cheaper in the near future, as large stocks are available, and its sale will decrease in proportion, as the sale of new synthetic drugs increases. In my opinion, prophylaxis, by the administration of any of the anti-malarial drugs, is of little value: the only prophylaxis of any use is that of destroying the infecting mosquito and curing those who are affected by the disease.

None of the poor and very few of the rich, even leaving aside the expense, are going to take for days or weeks on end, (1) quinine, which is very bitter, and makes the ears buzz, (2) plasmoquin, which may cause cyanosis, abdominal pain, sweating, or cardiac symptoms, or (3) atabrin, which may cause yellowness of the skin.

As regards treatment of the actual attack, my findings in this part of India differ from those given in the report and after trying various methods I have found the following to be the most efficient:—

As soon as malaria is diagnosed, quinine, in large doses—for an adult, 30 grains a day by mouth, or by injection, the latter in cases of vomiting, hyperpyrexia or coma. As soon as the fever is controlled, atabrin 0.1 gramme, t.d.s., for 5 days, combined with plasmoquin 0.01 gramme in cases of malignant tertian infection only.

It always seems to me cruelty to the patient to withhold quinine, until the temperature drops, as his agony thereby may be prolonged for days. By the treatment mentioned above I find that the fever is quickly controlled, and that relapses are infrequent.

Yours, etc.,

P. A. DARGAN,

MAJOR, I.M.S.,

Civil Surgeon, Dera Ghazi Khan.

DERA GHIAZI KHAN,
12th December, 1933.

[Note.—It has now become a well-recognized fact, and one, of which the Malaria Commission took full

account, that malaria reacts differently to treatment in various parts of the world; it is also true that, in the same part of the world, malaria caused by different species of plasmodium and malaria caused by the same species of plasmodium, but occurring in different individuals, react diversely to treatment.

Our correspondent agrees—but it is not clear with whom—that the “cinchona febrifuge” now obtainable is practically valueless. One of the points made by the report under discussion is that the expression ‘cinchona febrifuge’ has become meaningless; it has been applied to any mixture of the alkaloids. If therefore he means that valueless cinchona febrifuge is obtainable he is certainly right, but if he means that only valueless cinchona febrifuge is obtainable he is, with equal certainty, wrong.

It may be logically assumed that, from a medical point of view, the best devisable cinchona alkaloid preparation must be at least as good as quinine, but the more important point of view, as our correspondent appears to recognize, is the economic one. We do not however share his optimism regarding the fall of the price of quinine. Where a monopoly is concerned—and the Kinabureau does virtually control the world price of quinine—the law of supply and demand does not always operate, and the fact that there are large stocks does not mean that the price of quinine must inevitably fall. We hope, but so far it is little more than a hope, that the introduction of the synthetic anti-malarial compounds will cause a fall in the price of quinine. At present there is a heavy import duty on atabrin whereas quinine is free; this fact will not help to encourage the use of the former nor help to bring down the price of quinine.

The Commission were not dogmatic in their advocacy of any particular treatment routine, but in formulating their suggestions they took into account carefully-controlled treatment experiments that had been carried out in different parts of the world, and particularly those in India. Against such authority the impressions of individuals cannot carry much weight. The course of treatment advocated by Major Dargan seems to be a rational one, and it is one that is frequently advocated, but until very extensive, carefully-controlled, comparative experiments have been carried out it cannot be acclaimed as the best course.

Finally, we find it hard to believe that, in these days, anybody seriously advocates the withholding of treatment until the temperature falls as a routine measure; this meaning cannot be read into the recommendation of the Commission to delay specific treatment in certain circumstance.—EDITOR, I. M. G.]

A CALCULUS IN THE TONSIL

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In the issue of the *Indian Medical Gazette* of September 1933, Dr. S. C. Sarkar described a case of pea-sized concretion in the tonsil under the heading ‘A Calculus in the Tonsil’. He asserted that he could find no previous record of a stone in the tonsil.

I beg to draw your readers’ attention to the *Indian Medical Gazette* of April 1931, page 199, wherein Dr. M. R. Shah reported the case of a tonsillar calculus weighing 80 grains. I believe this is a record. I have this stone in my possession. I am now sending it to the Medical School Museum, Ahmedabad, for inspection of those interested.

Yours, etc.,

N. B. MAJUMDAR, L.M. & S.,
F.C.P.S. (Bom.), B.M.S.

CIVIL HOSPITAL,

KAIRA,

5th December, 1933.

[Note.—We do not, of course, accept responsibility for the statements of our contributors, but in this instance in publishing Dr. Sarkar’s note without comment we must plead guilty to having overlooked Dr. Shah’s paper.—EDITOR, I. M. G.]

EARLY SIGNS OF ARSENICAL POISONING

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—S, a Hindu, male, aged 38, consulted me for dark pigmented spots on the palms. Syphilis was suspected, and the Wassermann gave a positive reaction.

Anti-syphilitic treatment was commenced with 0.3 gramine of neosalvarsan, for the first injection. Ten minutes after the fifth injection (0.45 gramme of neosalvarsan) there was a thin discharge of serous fluid from the palms, something akin to beads of perspiration. This trivial incident was attributed to the drug being old stock, and the dose was repeated next week, but the same reaction was observed in an aggravated degree. The discharge ceased in less than half an hour, and the pigmented spots have disappeared after these five injections.

Is this a case of commencing arsenical dermatitis? Is it advisable to continue to give arsenic?

Yours, etc.,

P. N. VAIDYANATHA IYER, L.M. & S.

TRICHUR,

CENTRAL STATE,

SOUTH INDIA,

21st November, 1933.

[This letter was referred to Lieut.-Col. R. N. Chopra, C.I.E., I.M.S., Professor of Pharmacology, Calcutta School of Tropical Medicine, who reports as follows:—

‘In arsenical dermatitis, the flexor surfaces of the trunk and limbs, including the palms, are affected. The local reaction occurring with each injection seems therefore to be a toxic manifestation of arsenic. The special predilection in this case may be the result of individual susceptibility and of local condition present. The use of arsenic, therefore, needs caution’.—EDITOR, I. M. G.]

TEBETREN

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In your October number we notice an article by Lieut.-Col. R. N. Chopra and co-workers on the action of some synthetic anti-malarial remedies.

In this article the authors refer to ‘tabetren’; the correct name of this product is ‘tebetren’.

I shall be obliged if you will kindly draw attention to the error in your next issue and state that the product is manufactured by Messrs. Howards & Sons, Ltd., for the Proprietors Messrs. Chemopharm Ltd., 58, Victoria Street, London, S. W. 1.

Yours, etc.,

CHEMOPHARM LIMITED.

CALCUTTA,

31st December, 1933.

PLANOCAINE IN SPINAL ANALGESIA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I read with great interest Drs. Robinson and Seshachalan’s article on planocaine in spinal analgesia, in the *Indian Medical Gazette* of September 1933. In connection with this I am sending you the following extract from the *British Medical Journal* of 18th November, 1933, wherein planocaine is recommended only for short and minor operations.—

‘The opening meeting of the Section of Anaesthetics of the Royal Society of Medicine was held on 3rd November, when Dr. H. P. Fairlie delivered his presidential address on “Anaesthesia in Gynaecology”.

The president began by stating his reasons for having modified his views on the employment of chloroform in this type of work. He found he was using it less on account of its immediate and delayed risk. Gynaecological operations he divided into two classes—the minor and the major. For both classes he advocated the giving of morphine and nembutal orally as a

pre-medication. For the minor operations he contrasted the relative advantages of ethylene and oxygen, planocaine given as a spinal anaesthetic, and sodium evipan administered intravenously. The latter drug he found rather uncertain in its action, but suitable for short operations. For the major operations he favoured ether with oxygen, or spinal anaesthesia with percaïne'.

I should be very much interested to know Drs. Robinson and Seshachalam's views in the matter, as well as their experience regarding the administration of percaïne in preference to planocaine as advocated in the above extract.

One of the complications mentioned in planocaine administered is 'acute dilation of the stomach', from

which I infer that planocaine intra-spinal analgesia should be very strongly contra-indicated in stomach and intestinal surgery, even in hernia operations which the authors of the article under reference did not lay stress on.

Yours, etc.,

S. B. SURTI, F.R.C.S. (Ire.), D.P.H.,
Nizam's Medical Service.

CIVIL HOSPITAL,
NAMIPALLY,
HYDERABAD, DECCAN,

Service Notes

APPOINTMENTS AND TRANSFERS

MAJOR-GENERAL C. A. SPRAWSON, C.I.E., V.H.S., Officiating Director-General, Indian Medical Service, is confirmed in his appointment, with effect from the 15th November, 1933.

In supersession of previous notification Major-General H. R. Nutt, V.H.S., is confirmed in the appointment of Surgeon-General with the Government of Bombay, with effect from the 19th July, 1933.

Colonel D. P. Goil, Inspector-General of Civil Hospitals, Punjab, is appointed Surgeon-General with the Government of Bengal, with effect from the 1st December, 1933.

Colonel A. W. M. Harvey is appointed Honorary Surgeon to the King, 16th October, 1933, *vice* Brevet-Colonel J. McPherson, C.I.E., who has relinquished the appointment on retirement.

Colonel Sir Frank Connor, Kt., D.S.O., V.H.S., Assistant Director of Medical Services, Bombay District, is appointed Surgeon-General with the Government of Madras, with effect from the 20th November, 1933.

Lieutenant-Colonel R. Knowles, on return from leave *ex*-India, is re-appointed as Professor of Protozoology, School of Tropical Medicine, Calcutta.

Lieutenant-Colonel R. Knowles, Professor of Protozoology, School of Tropical Medicine, Calcutta, is appointed to act in addition to his own duties as Director of the said institution, *vice* Lieutenant-Colonel H. W. Acton, C.I.E., on leave.

Lieutenant-Colonel C. H. Reinhold, M.C., Civil Surgeon, Lucknow, is appointed to be Inspector-General of Civil Hospitals, Punjab, with effect from the date on which he assumes charge of his duties.

Lieutenant-Colonel A. J. H. Russell, C.B.E., Deputy Director-General, Indian Medical Service, is appointed as Public Health Commissioner with the Government of India, with effect from the 11th December, 1933, *vice* Major-General J. D. Graham, C.B., C.I.E., K.H.S., granted leave preparatory to retirement from that date.

Lieutenant-Colonel N. S. Sodhi, M.C., Civil Surgeon, Lahore, is appointed to officiate as Inspector-General of Civil Hospitals, Punjab, in addition to his own duties, with effect from the 24th November, 1933, until further orders.

Lieutenant-Colonel G. G. Jolly, C.I.E., is appointed as Deputy Director-General, Indian Medical Service, with effect from the 11th December, 1933, *vice* Lieutenant-Colonel A. J. H. Russell, C.B.E., appointed as Public Health Commissioner with the Government of India.

Major R. M. Kharegat, an Agency Surgeon, on return from leave, is posted as Agency Surgeon, Bundelkhand, with effect from the afternoon of the 15th November, 1933.

Major R. Hay, an Agency Surgeon, is posted as Civil Surgeon, Quetta, with effect from the afternoon of the 22nd November, 1933.

LEAVE

Lieutenant-Colonel J. C. De, Professor of Clinical Medicine, Medical College, Calcutta, is granted combined leave for 1 year from the 1st March, 1934, or date of availing.

Lieutenant-Colonel D. D. Kamat is granted, with effect from 1st March, 1934, leave, out of India, preparatory to retirement, on average pay for 7 months and 21 days, followed by such leave on half average pay as will bring the total period of absence to 28th February, 1935, inclusive.

In modification of previous notification, Lieutenant-Colonel V. N. Whitmore, O.B.E., Civil Surgeon, Simla West, was granted leave on average pay, with effect from the 17th November, 1933, to the 28th February, 1934. His services are placed at the disposal of the Government of the Punjab, with effect from the 1st March, 1934.

Major H. Williamson, O.B.E., an Agency Surgeon, is granted leave on average pay for 8 months combined with study leave for 3 months and 21 days and leave on half average pay for 6 months and 10 days, with effect from the afternoon of the 22nd November, 1933.

PROMOTIONS

Lieutenant-Colonel (temporary Major-General) Sir Leonard Rogers, K.C.S.I., C.I.E., retired, relinquishes the temporary rank of Major-General on ceasing to be employed and is granted the honorary rank of Major-General, 14th November, 1933.

Colonel Sir R. McCarrison, Kt., C.I.E., K.H.P., to be Major-General, 20th July, 1933.

Captain to be Major

T. A. Doran. Dated 27th November, 1933.

RETIREMENT

Lieutenant-Colonel F. B. Shettle, O.B.E., retires 25th November, 1933.

Notes

SPIRIT-PROOF CONTAINER FOR HYPODERMIC SYRINGE

By H. M. STANLEY TURNER, M.D., D.T.M. & H.,
F.R.S. (Edin.)

THERE must be quite a considerable number of medical men, especially those working in the tropics, who have been constrained to anathemize the usual type of spirit-proof containers for hypodermic syringes at some time or other.

To get over this difficulty I have designed a holder, which has been made for me by Messrs. Down Bros.

and has stood up to an extremely severe test. The cap fits on to the container by means of a long taper and is held in position by a detachable butterfly union nut. This mode of construction permits of the cap being accurately ground-in, so that an absolutely spirit-proof joint can be obtained. It is not necessary to screw the union nut down tightly, as it merely has to hold the cap, which as has been mentioned is completely spirit-proof, in position. A mere flick is sufficient.

I tested the holder by putting in 30 c.cm. of a saturated alcoholic solution of methylene blue and inverting it in a water bath at 75°C. (3.4° below the boiling point of alcohol) for six hours. At the end of that period there was no visible coloration of the water either to the naked eye or when compared with a specimen of the water, taken from the bath before the start of the test, in a Klett colorimeter. When cooled and measured the contents of the container measured

30 c.cm. To avoid all risk of the cone sticking, the act of unscrewing the union nut effects a 'primary extraction' by separating the male and female halves. The union nut beds into a layer of white metal on the cap and does away with the need for washers.

BAYER PRODUCTS

THE attention of our readers is drawn to the fact that the Havero Trading Company, the agents in India for the well-known firm of drug manufacturers, Bayer-Meister Lucius, have transferred their head office from Calcutta to Bombay; all correspondence should therefore be addressed to Havero Trading Co., Ltd., Commerce House, Ballard Estate, Bombay, or P. O. Box 642, Bombay.

SELF-RETAINING ABDOMINAL RETRACTOR

THE self-retaining abdominal retractor shown in the accompanying illustration gives wide and powerful retraction of the abdominal wall. The special advantages claimed for it are: (1) Simplicity of design: it does not require to be taken to pieces like some otherwise excellent retractors in order to go into the ordinary nursing-home sterilizer, with subsequent waste of the surgeon's time in re-assembling the parts. (2) Ease of manipulation: the blades are separated by compressing the handle with the *right hand only*, and the ratch is easily released when desired by gentle pressure with the right index finger on the under shank. This leaves the left hand free to manipulate the abdominal wall. (3) Smoothness of outline: it is entirely

free from projecting angles, knobs and thumb-screws which may entangle ligatures.

The retractor is useful for gynaecological operations and abdomino-perineal excision of the rectum. A special and unexpected use for the retractor is in performing a cholecystectomy through a paramedian incision. Lord Moynihan has pointed out that the placing of the left hand of the assistant 'in the exact position necessary to secure gentle traction of all the viscera away from the common duct is in many respects the most important single detail of the operation'.

Assistants are apt to remove that hand at the critical moment of the operation, when admittedly it is useful elsewhere. After the hollow viscera have been drawn to the left and covered with a moist gauze pack, the insertion of this self-retaining retractor will keep them out of the way as long as required and greatly facilitate the exposure of the common duct.

It is made in stainless steel by Messrs. Down Bros. Ltd., London, S. E. 1.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

FURTHER CLINICAL OBSERVATIONS ON POST-KALA-AZAR DERMAL LEISHMANIASIS

By L. EVERARD NAPIER, M.R.C.S., D.R.C.P.

and

C. R. DAS GUPTA, M.B., B.T.M.

Calcutta School of Tropical Medicine

We do not feel that any excuse is necessary for reporting our three years' further experience with this extremely interesting skin condition, post-kala-azar dermal leishmaniasis. Both writers are now engaged on other subjects, so that, as far as they are concerned, this paper will constitute a final clinical report.

From 1922, when the condition was first described, until the end of 1925 only odd cases cropped up, but from about November 1925 to the present date a steadily increasing stream of patients with these lesions have come to the School of Tropical Medicine for diagnosis and treatment. A series of 44 cases was reported by Acton and Napier (1927), and a second series of 150 cases by the present writers (1930); the latter series included patients that had attended up to the end of February 1930; the present series covers a period of three years from April 1930 up to the end of March 1933. During this period 209 patients with these skin lesions attended the kala-azar out-patient department; this probably does not include all the cases diagnosed in the School as there would be a certain number first seen in the skin or leprosy departments who, because they did not require treatment or for some other reasons, did not attend the kala-azar department. In nine of these 209 cases the records are inadequate and are not included in the following analysis.

The three reports will thus cover 394 cases, but they do not include the writers' whole experience of this condition, as cases have been seen both in Calcutta during periods not covered by these reports, at the village treatment centres (Napier, 1931) referred to here, in Assam (Napier and Smith, 1934) and in Madras (Napier and Krishnan, 1933); their total experience will amount to more than 500 cases.

Clinical types

The main types recognized are the same as described in our previous paper, and for detailed definitions reference should be made to it. The lesions were classified under the following headings:—

- Depigmented areas.
- Erythema or butterfly rashes
- Nodules.
- Verrucose types.
- Papillomatous types.
- Hypertrophic types.
- Xanthoma types.

The first three are the common types, in this series as in the previous ones; however, in the present series a greater proportion showed the depigmented lesions only, the erythema was noted more frequently and was also observed on parts of the body other than the face, and there were four cases with mucous-membrane lesions; these, with other abnormal cases, will be referred to later. In table I the cases are classified in groups according to the nature of the lesions.

TABLE I

Type of lesions

	NUMBER OF CASES IN WHICH LEISHMANIA		Total
	was found	was not found	
Mixed lesions (nodules plus other lesions)	55	61	116
Nodules only	10	3	13
Depigmentation and erythema	1	10	11
Depigmentation only	2	58	60
TOTAL ..	68	132	200

Nine photographs and one drawing of patients showing various types of lesions are here produced: Figures 1 and 2 are patients with extensive nodular lesions on the face; in the second the whole skin surface of the body was involved; both these patients had been diagnosed clinically as leprosy. Figure 3 shows a patient who has been under treatment on and off for many years; he has now got most extensive depigmented lesions on the body; the edges tend to be slightly raised and the small nodules are distributed over the depigmented areas. This is far from being a typical case.

Unusual clinical types

In this series we encountered all the clinical types mentioned above, with the exception of the 'xanthoma' type; there were in addition a few other types of lesions not hitherto described.

Mucous-membrane lesions.—In four cases they were definitely mucous-membrane lesions; the details of one are given briefly below:—

B M., Hindu male, aged 20, gave no history of kala-azar, but had 'typhoid' five years ago. His attention was drawn to his present condition one and a half years ago when he noticed a soreness of the roof of his mouth whilst eating; the condition has developed since this date.

Present condition.—He has a cauliflower-like growth on his hard palate, the centre of which is ulcerated; he has a butterfly erythema fairly well marked, and a few depigmented spots on his face, neck, chest, back and upper arms.

A snipping taken from the growth on the palate showed the presence of very large numbers of leishmania; they were far more numerous than is usual in a smear from a nodule (see figure 4).

The three other patients had raised nodular areas on the mucous-membrane surfaces of the

Fig. 1.

lips and cheek (figure 5); they were not ulcerated; smears from snippings showed leishmania in each case. In all these cases there were extensive nodular and depigmented lesions on various parts of the body.

Small ulcerated lesions.—One patient, an Anglo-Indian girl, aged 10, had a small ulcerated lesion on her nose. She gave a history of kala-azar two years before. She had depigmented lesions on other parts of her body. Leishmania were found in a smear made from material taken from the edge of the ulcer. She had never been out of Bengal, where *Leishmania tropica* infection does not occur. The lesion was not a typical oriental sore, but would have been accepted as one had it occurred in an endemic locality. The history and the presence of typical lesions in other parts of the body led to the diagnosis of post-kala-azar dermal leishmaniasis as against oriental sore.

The ulcer healed up slowly with antiseptic dressings and intravenous injections of neostibosan. It seems probable that this was a case

of some chronic bacteriological infection being superimposed on an area of skin infected with leishmania, and that the coexistence of the two infections was accidental. The incident is however exceptional, as there is usually rapid healing after the removal of a nodule for examination, and, as these snippings are taken under out-patient conditions, it is almost certain that the wounds are not always kept entirely aseptic.

Extensive erythema.—In two cases the erythema extended to other parts of the body; in one case the whole body was involved, and in the other only the lower limbs. Nodules were present in both cases, but not depigmented areas. Leishmania were demonstrated in both cases. The duration of the condition was long in both cases; in one it was given as 10 years; in this case there was no history of kala-azar, but only of fever with splenic enlargement.

Peri-onychial induration.—There was a suggestion of this in a number of cases, but in one

Fig. 2.

case it was definitely marked and leishmania were found in a smear from the lesion. Figure 6 demonstrates this condition which is not very different from the verrucose type already described, but in the latter there were definite warty growths rather than general peri-onychial thickening.

Associated conditions.—There were a few conditions which were almost certainly of

Fig. 3.

leishmanial origin as they were associated with other recognized leishmanial lesions; these were :—

Ichthyotic condition of the skin:—This was marked in two cases; in one the hands were involved (figure 7), in the other the feet.

Peeling of the skin:—In one case the whole of the skin of the soles peeled off.

Linear depigmentation:—In one case there were curious lines running vertically across the patella; the nature of the depigmentation was the same as that of the ordinary depigmented area, but was arranged in thin lines.

ANATOMICAL DISTRIBUTION OF THE LESIONS

This was much the same as in the previous series; an analysis of this distribution is given in table II.

HISTORY

History of prior attack of kala-azar.—In this series 82.5 per cent of cases gave a history of a previous attack of kala-azar; details are given in table III.

Incubation period.—In this series the time between the last symptoms of kala-azar and the appearance of the dermal lesions appears to be longer than in the previous series; the mean period was 1.88 years in the last series and is 2.32 years in this.

The mean duration of the depigmented lesions was 2.3 years, whereas that of the nodular lesions was 2.8 years. The difference in this series between the two groups is not so great as in the previous series; it indicates that time is not the only factor influencing the nature of the lesions. Details are given in tables IV and IVa.

Relationship to treatment.—Here a significant change has taken place in the distribution of the cases. In the last series in 47 per cent of the cases the treatment had been sodium antimony tartrate only, but in the present series this has dropped to 26 per cent; this, we assume, is nothing more than an indication of the increasing popularity of the pentavalent compounds in the treatment of kala-azar. It has at one time been said that the dermal lesions only occurred when insufficient treatment was given; there was no indication of this in the

Fig. 4

former series, nor is there any in the present one. Details are given in table V.

CLASS DISTRIBUTION

Caste and sex.—The proportion of males affected is a little higher in this series than in the last; the percentage, 86 per cent, is also higher than the percentage of males amongst our kala-azar cases. This possibly indicates that Indian men are more particular about their personal appearance than are women in Bengal. This is not so in the case of Europeans and Anglo-Indians; here the figures for the two sexes are about equal. Details are given in table VI.

Fig 5.

Age distribution.—This is given in table VII. Two facts are again clearly brought out in this table, namely, that if all types of lesions are grouped together the largest number are in the

third decennial age-group, whereas in kala-azar the largest number are in the second decennial age-group, and that in the case of those showing depigmented lesions only the peak of the age curve is in the second decennial age-group, whereas in those showing mixed lesions it is in the third.

The first fact is either the natural consequence of dermal lesions being delayed sequelæ of the generalized infection, or due to the greater susceptibility of older patients to the development of noticeable dermal lesions. The second indicates either that the depigmented lesions tend to appear earlier, or that they tend to take this form in younger patients.

DIAGNOSIS

In this series the number of cases diagnosed by finding the parasite was relatively less than in the previous series. The reason for this is that we have found that with experience it is possible to make a diagnosis clinically with absolute certainty. (It might be mentioned in justification for this statement that we have no natural leaning towards *clinical* diagnosis; on the contrary we always teach that it is *never* justifiable to make an unsupported clinical diagnosis of kala-azar.) In some cases no microscopic examination was made; in the majority a single smear from a nodule removed by means of a pair of sharp scissors was examined, and only in cases where there was any doubt about the diagnosis was a more thorough investigation—including cultural methods and sandfly feeding (*vide infra*)—undertaken.

The diagnosis in the cases with unusual lesions has in the first instance nearly always been determined by the presence of concomitant typical lesions; for example, the erythema would usually escape notice if there were not depigmented lesions also present, and it is

usually the latter that are first noticed by the patient. Nowadays, however, we are on the lookout for the characteristic erythema and we have recently encountered two cases in

Fig. 6.

which there were no other lesions present; in one of these, parasites were found by making smears from a small snip of skin, but in the

other we failed to demonstrate the parasite. In the second case the condition was thus possibly not due to leishmania, and an open diagnosis was made; neither case is included in this series. In all the cases in this series in

to 1932 was exactly 2,500 kala-azar cases; of these 29 or 1.16 per cent attended again with dermal leishmaniasis. Many patients developing dermal lesions will not have noticed them, others will have noticed them but not considered

which unusual lesions are reported, the parasites were found in these lesions themselves and not merely in the associated lesions.

We have in a few instances used sandflies as aids to diagnosis. The sandflies (*Phlebotomus argentipes*) are allowed to feed on the lesions, at intervals of 48 hours or so, they are fed again on an uninfected experimental animal on one or more occasions, and finally they are dissected and examined for leishmania. In one case, reported elsewhere (Napier, Smith, Das Gupta and Mukerji, 1933), the lesions were so undeveloped that they had not been noticed by the patient herself, and were overlooked by a number of medical men who examined her, yet a sandfly became infected with leishmania after feeding on her arm.

THE INCIDENCE OF DERMAL LEISHMANIASIS

The fact that the writers have now seen at least 500 cases of a disease that 10 years ago was considered an extremely rare condition indicates that the incidence is increasing. The attendance of cases year by year does not indicate any recent marked increase in the numbers, but there is as yet little sign of any decrease, whereas the kala-azar incidence wave has shown signs of declining for the last 10 years; the possible epidemiological significance of this has been discussed elsewhere (Napier and Krishnan, 1931).

The attendance at the kala-azar out-patient department at the School during the years 1927

Fig. 7.

them of sufficient importance to necessitate treatment, and yet others will have sought treatment elsewhere. The majority of our

patients are not permanent residents of Calcutta, and many come from distant parts of Bengal. It is therefore safe to conclude that the 29 patients who attended for diagnosis and treatment for dermal leishmaniasis are only a small fraction of the total number that developed these lesions.

In a village treatment centre near Calcutta where we had been treating kala-azar patients for some years, we collected 120 ex-patients, and examined them for dermal lesions; we found that six of these had definite dermal lesions; only one patient had noticed the lesions himself and drawn our attention to them.

These two sets of observations are in accord with one another; taking the incidence of dermal leishmaniasis as five per cent of treated kala-azar patients, we can readily believe that

lesions, and in five cases there was kala-azar in the family prior to the patients' attack of kala-azar. It is not possible to draw conclusions from these few figures, but they do appear to indicate that dermal lesions may be a source of infection to other members of the family.

Treatment.—There is not very much new to be said about treatment. It is not very satisfactory. Patients must always be prepared to undergo a much longer course of injections than they received for the original disease. Twenty injections, given twice or thrice weekly, must be looked upon as the minimum course. In some instances the nodular lesions will steadily shrink and the depigmented lesions will slowly assume the normal colour of the skin. The latter is always a slow process, and even in an early case it will be three or four months before it is completed.

Fig. 8.

Group of treated and cured kala-azar patients amongst which the six cases of dermal leishmaniasis, shown in figure 9, were found

only about a quarter of these would find their way back to us for treatment.

It will be seen from the two photographs that, though the population was a mixed one, all the patients developing dermal lesions were children (figures 8 and 9).

FAMILY HISTORY

In 23 instances there was a family history of kala-azar. The fact was noted in the routine examination of these patients, but only during the last year or so have more detailed enquiries been made regarding the time relationship of the patients' attacks with those of the other members of the family. It was ascertained that in five instances kala-azar occurred in the family after the appearance of the dermal lesions in the patient, in five there was kala-azar in the family at the time the lesions were first noticed, in two cases the kala-azar in the family occurred between the patients' kala-azar attack and the onset of the dermal

Fig. 9.

We have used neostibosan, aminostiburea, or urea stibamine in the majority of cases with some degree of success—we have a personal preference for the first-named; but we have found in some cases that resist treatment with the pentavalent compounds that trivalent antimonials, such as foudadin, give good results. In obstinate cases we have combined the antimony treatment with large doses of potassium iodide, with thyroid extract, with para-thyroid extract and with adrenalin. We have also used berberine sulphate locally, and leishmania vaccines. We have not had consistently good results with any one of these subsidiary forms of treatment, but our experience has been that even the most obstinate case will eventually clear up. By this time, however, the patient has usually received such a diversity of treatments that it has been impossible to say which brought about the cure. Thus, it has been impossible to make any scientific appraisal of the value of any of these subsidiary forms of treatment.

RELAPSES

A number of patients who have received insufficient treatment have come back later with their lesions in much the same condition as they were when they first attended, or perhaps showing slight signs of advancing, but few have shown definite relapses after being cured. The patient shown in figure 10 was an exception. He originally attended for diagnosis only; at that time he had a few nodular lesions on the face and a few depigmented areas on other parts of the body. He was given advice regarding treatment, he returned to his home where he was given a number of injections of neostibosan, and he considered himself practically cured; he then discontinued treatment but after a few months the present lesions appeared and developed rapidly. They were not the typical nodules, but red and vesicle-like, though of course they contained no free fluid. Histologically these nodules were the same as the typical ones, except that the covering epidermis was very thin.

DISCUSSION

During our last three years' experience of this condition no observations have been made that would lead us to make any serious alteration in our previously-formed opinions. That we should find new forms of this disease, we did not doubt, and it is equally certain that as time goes on yet others will be found. We have held the view that the depigmented and erythematous were the early lesions and that from them the nodules develop. This is frequently the history given by the patients themselves, and in the first series of cases analysed (Acton and Napier, 1927) this was clearly

indicated by the shorter histories in the cases showing depigmented lesions only; however, a reference back to tables IV and IVa will show that in this series there is less support for this view, as in many cases the depigmented lesions did not appear for three, four, and five years after the kala-azar attack and did not develop into nodules even after five years. It would appear that the age of the patient and the anatomical site are far more important factors in determining the nature of the lesions, though there is no doubt that in a certain number of cases the lesions do pass through the various stages of development that we indicated in our earlier papers.

Fig. 10.

The observations of a few cases in which there were lesions in the sub-mucous connective tissue does not in any way alter our conception of the disease; nor does the fact that in two cases, one a skin and the other a mucous-membrane lesion, ulceration occurred alter our definition of the condition as a non-ulcerating one, or in any way bring this condition into line with either oriental sore or the muco-cutaneous leishmaniasis of South America. In the case of the lesion on the palate, it is probable that the mucous membrane which was stretched over the nodule was repeatedly damaged by food in the mouth, and eventually broke down.

TREATMENT OF CHRONIC INTESTINAL AMOEBIASIS WITH GAVANO, A DERIVATIVE OF IPECACUANHA

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

S. SEN, M.B., D.T.M.

and

B. SEN, B.Sc., M.B.

(From the School of Tropical Medicine, Calcutta)

ONE of the most difficult problems with which a medical practitioner in the tropics has to deal is the treatment of chronic intestinal amoebiasis. Amoebic dysentery is very common in India. A routine examination of the stools of patients admitted into the Carmichael Hospital for Tropical Diseases showed an incidence of 12 per cent of infection with *Entamoeba histolytica*. Chronic intestinal amoebiasis as a cause of sickness and invaliding in this country is of great importance, especially among the European community. An acute attack of amoebic dysentery can, in the majority of cases, be successfully relieved by proper treatment, but eradication of chronic intestinal infection with *E. histolytica* is a difficult matter. Most of the remedies used reduce the infection to a low level so that the patient's own powers of resistance can keep in check the parasites which still remain in the body. Emetine although it is an excellent drug for the treatment of amoebic dysentery often fails to cure the chronic carrier condition. It has been said that emetine cures about one-third of the cases, one-third improve, and in the remaining third the drug has no effect at all. When actual symptoms of

dysentery are present, the amoebæ are numerous and in full activity, yet they are amenable to the action of emetine. The reason is that the gut in that condition is hyperæmic and any emetine circulating in the blood will have ready access to the amoebæ. The most resistant are the chronic cases that get relapse after relapse and fail to react to this drug. In these patients there is superficial ulceration or even considerable thickening and fibrosis. The amoebæ are said to be walled in and it becomes difficult for emetine to act on them. Why entamoebæ can be readily eradicated from one individual and become firmly established in another is difficult to say. The influence of the environment on the vegetative forms of *E. histolytica* is believed to be an important factor in the encystation. It is possible that these factors also play a part in the carrier problem and also prevent emetine from producing its usual destructive effect. The position of emetine with regard to chronic amoebic dysentery can be summed up as follows:—

(a) Emetine is a toxic drug and it is not possible to give it in sufficient amounts and over sufficiently prolonged periods to destroy all the parasites. The encysted forms appear to be especially resistant to it, but it gives symptomatic relief in the majority of cases. (b) Emetine cannot be brought by colonic irrigation into contact with amoebæ deeply seated in ulcers. (c) The presence of secondary bacterial infection is an important factor in preventing cure. When amoebic and bacillary dysentery, especially of the Flexner type, coexist, the reaction of the gut becomes very acid and emetine cannot efficiently act in an acid medium. (d) In bacillary dysentery (Shiga type) the reaction of the gut may be alkaline to litmus (pH 8.11), in the amoebic form the pH of the stools is 6.3. It is found that when the pH of the contents is 7.0 the amoebæ are dead or dying; cyst formation occurs when the pH of the contents is 7.24; Charcot-Leyden crystals are passed at 6.96. The acid reaction hinders the action of emetine which works better in an alkaline medium. Attempts at markedly raising the alkalinity of the contents of the large intestine by giving alkalis by the mouth have not met with much success. Injections of emetine probably fail on account of the alkaloid not being in sufficient concentrations to be effective in the acid contents of the large gut. The stool in such cases are usually at pH of 6 or less and this means that emetine would have to be in a concentration of 1 in 10,000 or thereabouts to be effective on the amoebæ in this substrate. Efforts were therefore made to prepare compounds which could be given by the mouth so that higher concentrations could be obtained in the intestines. Emetine bismuth iodide was the first of these compounds. Although a distinct advantage is gained by giving emetine in this form, experience has showed that this compound is toxic and cannot be given in large enough doses.

- Napier, L. E., Smith, R. O. A., Das Gupta, C. R., and Mukerji, S. (1933). The Infection of *Phlebotomus argentipes* from Dermal Leishmaniasis. *Indian Journ. Med. Res.*, XXI, 173.

One course often fails to affect a cure and a second and more intense course, of longer duration, has to be given. Even then a large residue of cases is left in which infection is not eradicated.

Another derivative of ipecacuanha was emetine adsorbate or 'Alkresta ipecac' which is an adsorption compound of the total alkaloids of ipecacuanha with hydrated aluminium silicate or fuller's earth. The advantage claimed for this compound was that it had no irritant effect on the gastric mucosa and therefore larger quantities of emetine could be introduced by the mouth and a higher concentration obtained. The drug is certainly well tolerated by patients, and its administration is not followed by diarrhoea and vomiting, as is the case with emetine bismuth iodide, but it is not effective in eradicating the entamoebæ.

Recently another derivative of ipecacuanha has been prepared by Messrs. Bayer-Meister Lucius under the name of *Gavano*. It is apparently a derivative of emetine (mono-methyl ester of cephaeline) or cephaeline itself. It is said to be a combination with an organic acid, the nature of which is not disclosed. The idea

of this preparation probably is to do away with the irritant and toxic effects of emetine so that the drug may be administered by the mouth in fairly large doses. With a view to testing its efficacy we tried this drug in a series of cases in the Carmichael Hospital for Tropical Diseases. The patients were all admitted under the senior author and most of them were chronic sufferers. The drug was given, as recommended by the makers, in doses of one tablet thrice daily for six consecutive days or one tablet twice daily for nine consecutive days. No restrictions were observed regarding diet but the bowels were kept open. The pulse rate was carefully recorded and the urine was examined daily while the treatment was going on and also for some days after the treatment was discontinued. Some of the patients had a mixed infection with bacillary dysentery and, in these, autogenous vaccines were given along with treatment by *Gavano*. The criterion of cure applied was six negative examinations after the cessation of treatment, this being the only one possible under the circumstances. The following table gives briefly the results we obtained:—

Table of cases treated with *Gavano* (a derivative of ipecacuanha)

No.	Race, sex, age	Duration and previous treatment	Laboratory findings before treatment	Treatment	Laboratory findings after treatment	REMARKS
1	I. Ch., F., 28	2 years ..	Scanty <i>E. h.</i> veg. and cyst, blastocystis, <i>E. coli</i> cyst, streptococci, <i>Salmonella morgani</i> , hookworm, ascari and trichuris ova.	I. <i>Gavano</i> 1 tab., b.d., for 9 days. II. Autovaccine (<i>Sal. morgani</i>) one course.	Negative 6 exams.	Cured.
2	A.-I., M., 10	5 months ..	Scanty <i>E. h.</i> cyst, giardia cyst, C.-L. crystals, blastocystis, streptococci.	I. <i>Gavano</i> ½ tab., b.d., for 9 days.	<i>E. h.</i> cyst.	Failed.
3	A.-I., F., 27	No intestinal symptoms. Pain in back, fever and unhealthy skin 6 years.	Very scanty <i>E. h.</i> cyst, hookworm, ascari and trichuris ova.	<i>Gavano</i> 1 tab., b.d., for 9 days.	Negative 6 exams.	Cured.
4	A.-I., F., 59	Present attack 5 days; gall-stones 2 years ago; diabetes 1 year ago.	Scanty <i>E. h.</i> veg. and cyst, blastocystis, <i>Salmonella morgani</i> .	I. Do. II. Autovaccine (<i>Sal. morgani</i>) one course.	Very scanty <i>E. h.</i> veg.	Failed.
5	M., M., 30	Originally admitted for malaria. No dysentery symptoms.	Scanty <i>E. h.</i> veg., <i>E. nana</i> cyst, blastocystis.	I. <i>Gavano</i> 1 tab., b.d., for 9 days.	<i>E. h.</i> veg., blastocystis.	Do.
6	H., M., 20	Do.	<i>E. h.</i> veg., C.-L. crystals, cellular exudate, hookworm ova.	<i>Gavano</i> 1 tab., b.d., for 9 days.	Negative 6 exams.	Cured.
7	M., M., 40	8 years ..	Scanty <i>E. h.</i> veg. and cyst, trichomonas, hookworm and trichuris ova.	Do.	<i>E. h.</i> veg.	Failed.
8	H., M., 45	2 months; treated for chronic bacillary dysentery some time ago.	Scanty <i>E. h.</i> veg., <i>E. coli</i> cyst, <i>I. butschlii</i> cyst, <i>E. nana</i> cyst.	<i>Gavano</i> 1 tab., t.d.s., for 6 days.	Negative 6 exams.	Cured.

Table of cases treated with Gavano (a derivative of ipecacuanha)—concl'd.

No.	Race, sex, age	Duration and previous treatment	Laboratory findings before treatment	Treatment	Laboratory findings after treatment	REMARKS
9	H., M., 27	8 months; emetine with temporary relief.	Scanty <i>E. h.</i> veg., trichomonas, streptococci, epithelial cell, degenerated polymorph and few r.b.c.'s. Urine: a trace of albumin, bile.	Gavano 1 tab., t.d.s. for 6 days.	<i>E. h.</i> veg.	Failed.
10	M., M., 20	Originally admitted as a case of kala-azar.	<i>E. h.</i> veg. and cyst, <i>E. nana</i> veg. and cyst, chilomastix, blastocystis, hookworm and trichuris ova. Urine: albumin.	Gavano 1 tab., b.d., for 7½ days.	Negative 2 exams.	Flatulence, Gavano stopped after 7½ days. Indeterminate. Cured.
11	H., M., 31	3 months ..	Scanty <i>E. h.</i> veg. and cyst.	Gavano 1 tab., b.d., for 9 days.	Negative 5 exams.	Failed.
12	M., M., 14	2 years ..	<i>E. h.</i> cyst, <i>E. coli</i> cyst, hookworm ova.	Do.	Very scanty <i>E. h.</i> cyst, <i>E. nana</i> cyst, blastocystis, degenerated polymorphs, few epithelial cells, yeasts.	
13	A.-I., M., 15	Few <i>E. h.</i> veg. and cyst, <i>E. nana</i> cyst, blastocystis, trichuris ova.	Do.	Negative 3 exams.	Indeterminate.
14	H., M., 20	2 years ..	Scanty <i>E. h.</i> veg., <i>B. pseudo-carolinus</i> .	I. Gavano 1 tab., b.d., for 9 days.	Negative 6 exams.	Cured.
15	A.-I., M., 9	3 weeks ..	<i>E. h.</i> veg., cellular exudate, yeasts, trichuris ova.	II. Antovaccine Gavano ½ tab., b.d., for 9 days.	Scanty <i>E. h.</i> veg.	Failed.
16	A.-I., F., 46	1 year, emetine	<i>E. h.</i> veg., C.-L. crystals, cellular exudate.	Gavano 1 tab., b.d., for 7 days.	<i>E. h.</i> veg.	Do.
17	E., M., 38	6 months ..	<i>E. h.</i> veg., C.-L. crystals, cellular exudate, <i>B. pseudo-carolinus</i> .	Gavano 1 tab., b.d., for 9 days.	Scanty <i>E. h.</i> veg.	Failed (drowsiness).
18	A.-I., M., 51	3 months ..	<i>E. h.</i> veg., cellular exudate, <i>B. pseudo-carolinus</i> .	Gavano ½ tab., t.d.s., for 6 days.	<i>E. h.</i> veg.	Failed.

 C.-L. crystals = Charcot-Leyden crystals.

A perusal of the table will show that 6 patients or 33.4 per cent were cured; in 10 patients or 55.5 per cent the drug failed and 2 or 11.1 per cent were indeterminate. The proportion of probable cures to failures in this series is 1:1.66. In the doses prescribed the drug did not produce the toxic effects of emetine. In two cases slight albuminuria was observed, but the drug does not appear to have any marked irritant effect on the kidneys or the liver. The only visible ill effects produced by the drug were a feeling of discomfort, sometimes amounting to pain, in the epigastriac region, flatulence, heaviness in the head, and occasionally a feeling of drowsiness. Nausea, vomiting and diarrhoea were not seen

in this series. The drug produced no appreciable effect on the pulse or respiration.

Summary and discussion

Gavano is said to be a derivative of ipecacuanha and is believed to be a compound of emetine or cephaeline with an organic acid. It can be taken by the mouth without the nausea and vomiting usually produced by emetine. In therapeutic doses in a series of cases of chronic amoebiasis the drug did not produce any toxic effects on the circulatory and nervous systems, but its amoebicidal properties were not so good as emetine bismuth iodide, the kurchi alkaloids,

OBSERVATIONS ON A CASE OF COCCIDIAL INFECTION IN MAN (*ISOSPORA BELLI* WENYON, 1923)

By ASSISTANT SURGEON B. M. DAS GUPTA, L.M.P.
Assistant Professor of Protozoology, Calcutta School of Tropical Medicine

HUMAN coccidiosis is a rare disease. Altogether about 150 cases have been described in the literature.

Cragg (1917) reported 4 cases from Bombay, but all these patients contracted the infection in the Mediterranean War area.

Knowles (1928) was the first to show that coccidiosis in man exists in India. He discovered very scanty oöcysts 5 times in the mixed faeces of sweepers employed in the various departments of the institution. These men are chiefly natives of Bihar and Orissa. As it has been found that sweepers' stools afford a very rich material for the study of intestinal protozoa, these are collected, mixed together, emulsified in salt solution and supplied to the D. T. M. and L. T. M. classes for the purposes of study.

It is not unlikely that the stool of the same individual harbouring the infection was examined more than once, for it was not possible to single out the infected person or persons.

(Continued from previous page)

or carbarsone. Trials of this drug in acute amœbic dysentery and where the liver is affected may show its utility in these conditions. Neither the kurchi alkaloids nor carbarsone, two of the most effective drugs against chronic amœbiasis, have any effect on liver conditions associated with amœbiasis. Emetine is the only known drug that will abort a threatened liver abscess. Gavano can be administered by the mouth without producing nausea and vomiting and without producing toxic effects on the heart. It is possible that this drug or an allied compound may give us a less toxic drug than emetine for such conditions.

We are very grateful to Messrs. Bayer-Meister Lucius for supplying us with this compound for clinical trials.

The present case was detected on the 2nd December, 1933. The patient is a young Bengali Brahmin.

Previous history.—He has never been abroad. In December, 1925 he had an attack of dysentery from which he recovered after a course of emetine injections. In 1930 he had a similar attack for which he did not seek medical advice. The symptoms disappeared spontaneously.

In March 1932 he developed severe diarrhoea, the stools were voluminous, frothy and slimy. The symptoms persisted for about two weeks. On no occasion were the stools examined.

Present condition.—On the 1st December, the patient was awakened with pain in the abdomen, and diarrhoea. The temperature went up to 99.4°F. on one occasion only. The first specimen of stool was received in the laboratory on the following day.

During the period of the 2nd December to the 8th December, the stools were liquid and slimy in appearance. The motions were frequent.

From the 7th to the 12th the frequency of the stools was diminished, but they were copious and frothy, with flakes of mucus.

During the period the 13th to the 20th December, the stools gradually became formed. Occasionally streaks of mucus were adherent to the formed mass.

Laboratory findings.—The stools were examined daily from the 2nd to the 20th December. Oöcysts were present in fair numbers from the 2nd to the 5th and after that period they gradually decreased in number till they disappeared altogether on the 20th December. From the 6th onwards the oöcysts were so scanty that they could only be detected by the application of concentration methods. Of the various methods advocated by Cropper and Row (1917), Sheather (1923) and Willis (1921), the last-named technique was found most convenient for the purpose, although a certain amount of distortion of the oöcysts takes place owing to shrinkage of the cyst wall, if kept too long in the saturated salt solution.

No other protozoa were found on any occasion, scanty ova of *Trichuris trichura* were found in almost every specimen. Charcot-Leyden crystals were present in large numbers at the beginning, but lessened gradually though a very few crystals were still found in the last specimen examined. No inflammatory cell exudate other than a few desquamated epithelial cells were present on the first two or three days. Every specimen examined showed soap crystals in abundance.

Fresh specimens were plated daily from the 3rd to the 10th December, but on no occasion were organisms of the dysentery group isolated. The serum of the patient during convalescence was also tested against *B. flexner* and *B. shiga*, but no agglutination reaction was obtained.

The parasite.—The oöcysts vary from 25 to 29 microns in length with a characteristic appearance. Specimens kept at room temperature for three days showed the development of typical sporozoites within the sporocysts. The oöcysts were very scanty and were detected only after concentrating, except during the acute stage of the illness when they were present in fair numbers. This shows that, if concentration methods are used for finding the oöcysts, it is possible that a greater incidence might be revealed.

Treatment.—No treatment was given. The symptoms subsided with the diminution in the number of the parasites.

Summary

A case of coccidiosis in a Bengali who has never been abroad is described.

There was severe diarrhoea accompanied with abdominal discomfort, lasting for about a week.

Oöcysts were present in the stools for 18 consecutive days, although they were scanty, except during the acute manifestation of the disease.

Of the concentration methods employed, the one advocated by Willis (1921) for concentration of ova was found most suitable for the purpose.

Charcot-Leyden crystals were persistently present throughout the whole investigation.

No other cause apart from infection with the *Isospora* could be discovered to account for the illness.

I am indebted to Lieut.-Col. R. Knowles, I.M.S., my chief, for his valuable suggestions and to Dr. K. Chatterjee for the history of the patient and the material.

SPONTANEOUS PNEUMOTHORAX

By R. VISWANATHAN, B.A., M.D., M.R.C.P. (Lond.)
Government General Hospital, Madras

Definition

THE name is given to the condition where air enters the pleural cavity spontaneously, usually as a result of the rupture of the wall of an alveolus.

As early as 1856 M'Dowell described cases of pneumothorax occurring not only in people with pre-existing pulmonary disease but also in apparently-healthy individuals. Cases have been reported in the literature from time to time, and, recently, Kjaergaard (1932) collected a series of 51 cases of spontaneous pneumothorax in the apparently healthy. I have seen several cases of pneumothorax in tuberculous patients, but recently I came across two cases in apparently-healthy individuals; reports of these cases are given below.

Ætiology.—In some rare cases it occurs as a very early sign of commencing lung lesion, but more often during the advanced stages of phthisis. It might also occur as a complication of non-tuberculous diseases of the lungs,

such as carcinoma, abscess, gangrene, or emphyema.

The occurrence of spontaneous pneumothorax in the apparently healthy is in all probability due to rupture of an emphysematous bulla, as shown in six of Kjaergaard's cases that came to autopsy. It is a matter for surprise that pneumothorax rarely occurs in general emphysema. The mechanism of production is something like this. A valvular opening connects the vesicle with a bronchiole in such a way that air can enter the vesicle but cannot leave it. The bulla gets more and more distended until it bursts ultimately, resulting in the free passage of air from the lungs to the pleural cavity. In most cases the opening closes as the vesicle collapses, and the accumulated air is soon absorbed, but if the valvular opening persists, and the integrity of the valve action is maintained, the interpleural pressure rapidly increases, causing considerable discomfort to the patient. If not relieved by repeated aspiration of air, the patient may die of shock or insufficient pulmonary ventilation. In some cases a fistulous free communication persists; in this case a permanent pneumothorax occurs which may cause no evident distress to the individual.

It is more common in men than in women, as shown by Kjaergaard, 36 of whose 51 cases were men. Thirty-six of his cases were between 20 and 40 years of age; 33 occurred on the right side, 17 on the left, and one was bilateral.

In both my cases the patients were men of apparently strong constitution 24 and 22 years of age, respectively. The right side was affected in one, and the left side in the other.

Symptoms.—It is quite probable that there are a large number of cases of pneumothorax in which the condition is partial; these go unrecognized owing to the absence of marked symptoms. In some cases of advanced tuberculosis with considerable pleural adhesions, partial pneumothorax might occur without causing any additional distress to the patient. Ordinarily when complete pneumothorax occurs spontaneously the patient complains of sudden pain on the side of the chest affected, with a varying amount of dyspnoea. If there is considerable increase of interpleural pressure with displacement of the mediastinum, there will be cyanosis as well. Rarely, death occurs as a result of shock or lack of oxygenation of the blood. Most patients make an uneventful recovery, sooner or later, as the air gets absorbed, but if one of the blood vessels also ruptures along with rupture of an emphysematous bulla, fatal hæmopneumothorax may occur, as in the cases reported by Rolleston (1900) and Newton Pitt (1900). Burrell (1932) is of opinion that if effusion complicates spontaneous pneumothorax, there is sure to be a pre-existing disease of the lung, most probably tuberculosis. In the apparently healthy, effusion hardly ever occurs.

Both the cases reported below recovered rapidly and completely, as the x-ray plates show.

Case (a).—A medical student, aged 24 years, apparently in the best of health, had a sudden catch over the right side of the chest while bending back in the act of yawning. I saw him about twelve hours after the incident. He had considerable pain over the whole

of the right side of the chest, difficulty in breathing and inability to lie on the right side. I proceeded to examine him with the biased idea that it would be a case of pleurisy, but on systematic examination I found deviation of the trachea to the left, displacement of the heart to the left, absence of vocal fremitus and vocal resonance, with tympanitic note on percussion and absence of breath sounds on the right side. Bruit d'airain, so characteristic of pneumothorax, also was

Case (a) 2nd day.
The collapsed lung is outlined.

Case (a) 15th day.
After the lung had expanded again.

present. X-ray showed complete collapse of the lung on the right side. Owing to his being in distress, I removed one litre of air; this gave him almost immediate relief. X-ray ten days later showed almost complete absorption of air from the pleural cavity. The lungs were apparently normal, and he did not exhibit any symptoms pertaining to disease of the lung.

Case (b)—A deck-hand, aged 22 years, had a sudden pain on the left side of the chest during the ordinary

course of his duties. He was sent to the Royapuram hospital with a diagnosis of pleurisy with effusion, four days later. X-ray examination revealed partial pneumothorax on the left side. He had no distress whatsoever. He showed complete absorption on examination by x-ray ten days later. The lungs were apparently in a healthy condition.

THE ACID AND SANITOL TREATMENT OF THE INTESTINAL FLUXES

By F. J. PALMER, F.R.C.S.I.

LIEUTENANT-COLONEL, R.A.M.C. (ret'd.)

P. O. Hooprijan, Upper Assam

IN 1924, the writer published a paper on the treatment of cholera by cresol, and in the following year, 1925, a further paper in which he described what seemed to him the better results

(Continued from previous page)

Diagnosis is easy when the pneumothorax is complete. Hyper-resonance with absence of breath sounds and displacement of the mediastinum to the opposite side are quite characteristic, it may be difficult if the air cavity is encysted as in advanced phthisis. If there is only partial pneumothorax confined to the upper portion of the pleural cavity, as in the second of the cases reported above, the relative difference in resonance between the upper and lower portions might lead to the mistaken diagnosis of pleural thickening or effusion at the base. X-ray examination, of course, will clinch the diagnosis.

The prognosis depends on the ætiological factor. When it occurs in the apparently healthy, recovery is certain except when it is associated with fatal shock, or fatal hæmorrhage. Pyopneumothorax resulting from rupture of an abscess will often recover after energetic treatment. When pneumothorax occurs in the early stages of tuberculosis, it may be considered as a desirable accident, since it will produce collapse of the lung. In the advanced stage it often results in pyopneumothorax which makes the prognosis of the condition worse.

Treatment.—If it occurs in the apparently healthy, no treatment is required, unless the patient is considerably distressed, when aspiration of air is indicated. In acute tuberculosis it is advisable to maintain the collapse of the lung with refills, but, if pyopneumothorax occurs, Burrel advocates aspiration and washing out of the pleural cavity with Dakin's solution. In resistant cases obliteration of the cavity can be done only by resorting to thoracoplasty.

[Note.—Attention is drawn to the report on a case of pneumothorax, by H. W. Acton and Darmendra, in our issue of May 1933.—EDITOR, I. M. G.]

obtained by the addition of acid to the cresol. This was followed by a third paper in 1928, in which the dosage of acid was somewhat increased, and sanitol recommended.

The sanitol used should be as fresh as possible, as when kept for some time, and especially if exposed to air, the solution, or, more strictly speaking, the emulsion, becomes of slightly brownish colour, instead of the milky-white emulsion formed when fresh sanitol is added to water.

When the mixture is of this colour it may be found that minute tarry globules appear on the surface shortly after the addition of acid, when the sanitol is quite fresh this only occurs after a considerable interval.

Why acid has not been used of recent years in the treatment of the more severe intestinal fluxes is difficult to see, but it was probably due to the fear of inducing acidosis, and this it was which at first deterred the writer, until he found it to be a more or less negligible bug-bear in such cases.

It has long been known that the cholera vibrio is susceptible to acid, as is also the food poisoning, the Salmonella, group, which is extremely susceptible, and the writer claims to have proved clinically that to these may be added the dysentery bacilli, and those other members of the great group of colon bacilli which produce so many of the infective diarrhæas.

The use of acid is no new thing for the treatment of diarrhæa. The old clinicians used it, and an acid mixture was, it is understood, in use for the treatment of cholera by the surgeons of the Company days. When the writer first came to India, quite an effective *mistura pro diarrhæa*, containing acid, was in the medical panniers of those days.

The clinical observations of these older physicians was sound, but their explanation that the good effects of acid were due to its astringent action was incorrect. The beneficial effects are due to the inhibiting effect produced upon the unbridled growth of the infecting organisms in the bowel.

The older explanation is still current, however, in many works on therapeutics and materia medica.

Since contributing the earlier papers the writer has gradually increased the dosage of acid, as he found his fears of acidosis more or less groundless. There is far more acidosis induced by an unbridled intestinal flux, than by the acid used in conjunction with a weak antiseptic to check it. During the continuance of the flux, the current is from within outward, and little absorption appears to take place.

It is now proposed briefly to recapitulate the treatment and explain the guiding principle, giving a résumé of its use in the various intestinal fluxes, with the difficulties encountered, and the results based on the experience of many years of treatment by one method, in many hundreds, if not over a thousand, cases.

The guiding principle is to wash out the intestine in all infective bowel fluxes with a weak solution of sanitol of constant strength, reinforced by the addition of acid. This solution is of constant strength as regards sanitol, and variation of dosage according to age is obtained by varying the amount given.

The amount of acid varies with the age or size of the patient, and a little consideration will show that in this way the dosage is more or less in proportion to the area of bowel to be treated.

These doses are washed down by draughts of tepid water in the more acute fluxes, the result obtained being, as it were, to flush out the intestine with a weak bactericidal and growth-inhibiting solution, much as we would flush out a drain.

To grasp fully the ideas underlying the treatment, a study of the previous papers on the subject would be an advantage to those interested in the subject, for they form a definite sequence.

This method of treatment is not meant to apply to amœbic dysentery, but is of otherwise general application to almost every case of infective diarrhœa, through the gamut of simple diarrhœa, the choleraic diarrhœas, food poisonings, and bacillary dysenteries.

The dosage is as follows :—

Ages, in years	Cresol, in minims	Acid. sulph. aromat., in minims	Water, in ounces
1 to 3	1	4 to 6	1
3 to 6	2	6 to 8	2
6 to 9	3	8 to 10	3
9 to 12	3	10 to 12	3
12 upwards	4 to 5	12 to 20	4

The cresol dilution should be made up as freshly as possible and the acid, where possible, only added immediately before administration. A pipette may be used for making up the mixture.

In some cases it may be necessary, for convenience, to make up the cresol solution in one bottle, and the acid in another, marking the doses by the usual strips of paper, and leaving the relatives to administer the doses, but this should be avoided as much as possible.

The method, as employed in cholera, food poisoning, the choleraic diarrhœas—or the clinical choleras, as the writer prefers to call them, for he recognizes more than one variety—and the more acute and fulminating dysenteries, is as follows :—

The above doses according to age are given every quarter of an hour for eight doses, and thereafter every half hour for four doses, the treatment thus taking up four hours, during which twelve doses are administered, eight in the first two hours, and four in the second two

hours. The acid is then omitted, and sanitol alone in appropriate age dosage is given every hour for the next twenty-four hours.

In previous papers, for fear of acidosis, sanitol only every second hour on the next day was recommended, and on the third day three hourly. With greater experience I see no objection to giving the acid and sanitol mixture every second hour next day, and three-hourly on the third day.

This is the ideal to be aimed at, and can generally be more or less obtained, but it should be borne in mind that if, for any reason, there is difficulty in administration or retention, it is better that weaker, smaller, or less frequent doses be given, and retained, than that stronger, larger, or more frequent doses be attempted and rejected.

If nausea and vomiting are present, retention can generally be assured by administration for adults of tinctura chloroformi et morphinæ co., minims 15, tinctura opii minims 20 to 25, or the injection of $\frac{1}{4}$ grain of morphia hypodermically.

The patient is encouraged to drink small quantities of tepid water at frequent intervals between doses if possible, this lessens the irritation of the medicine, and increases intestinal lavage and voiding of toxic bowel contents, and may add some much-needed fluid to the system, should stomach absorption recommence as the toxicity lessens.

It will be observed that the strength of sanitol never varies, but remains one minim to an ounce of water, to keep gastric irritation at a minimum and secure retention.

The choleraic diarrhœas,* food poisonings, and the fulminating dysenteries should be treated in the same way as cholera, and should collapse be severe in any of them, transfusion may be given in addition. In simple diarrhœas administration four to six times daily will suffice. As the severity of the diarrhœa with which one has to deal increases, it will be found that a more frequent dosage is required to check it, so that doses six, eight, or ten times in the 24 hours may be required, until in the most severe cases one reaches the necessity for the same intensive treatment as in cholera.

In the diarrhœa, choleraic diarrhœa, and food poisoning groups, the treatment is definitely specific, and no case is lost which is admitted

[* In his original typescript the writer used the expression 'the choleras', a term that he considers should be used to cover the large group of acute intestinal disturbances of mixed ætiology that are encountered in his tea-estate practice; in his opinion some of these are true vibronic cholera. As the word 'cholera' has acquired a specific significance, we have, with the author's permission (though not altogether with his approval), modified his paper and introduced the expression 'choleraic diarrhœa'. We do not, however, question the writer's statement that some of the cases are true cholera and that these react as well to his treatment as do the acute dysenteries of non-vibronic origin.—EDITOR, I. M. G.]

before deep collapse has taken place. In these cases in which all the infection is within the bowel, and there is comparatively little destruction of the bowel wall, the antiseptic treatment is easier of application than in the dysenteries where marked destruction of bowel wall may have taken place. The writer pointed this out long ago, and the point has recently been stressed by McCay (1932).

As I have stated, this method of treatment is applicable to the great majority of diarrhoeas, and the diarrhoea which sometimes occurs with influenza or malaria is best treated by some four to six doses or more of the acid antiseptic mixture daily.

The enteritis which is often such a dangerous sequela of measles is also greatly benefited by a similar line of treatment and, in 1930, twenty-one such cases were treated by the Indian doctor of one of the writer's gardens with only one death. In the previous year, before this treatment was adopted there were many deaths from this cause.

The diarrhoea of enteric fever when severe is often greatly benefited and lessened by a few doses of the mixture, which probably acts in most of these cases by checking the increased multiplication of the more toxic members of the *coli* group that occurs whenever the contents of the bowel become more fluid in character.

In endeavouring to explain the application of the method of treatment in dysentery, one is up against a much more difficult problem than in the class of case already considered.

Whilst in the great group of diarrhoeas, choleraic diarrhoeas, and food poisonings, there is little structural damage to the bowel beyond a catarrhal inflammation easily repaired if the cause be checked, in the dysenteries actual destruction of the intestinal mucosa occurs only after the disease has lasted for a short time.

The more severe types of bacillary dysentery are febrile and it is the writer's experience that, if fever has lasted with first discomfort and then gradually increasing pain in the abdomen for two or three days before, the motions become frequent, and contain blood and mucus.

At this stage the involvement of the mucosa is presumably not severe, and confined either to the surface or a small area of the bowel, and the effect of treatment on the lincs already indicated is generally dramatic. The temperature falls rapidly to normal, the number of stools quickly decreases, and I have seen such patients pass a semi-solid stool with a slight trace of mucus, or perhaps even none, within three days.

And the improvement is not only confined to the milder cases; the fulminating cases often do extremely well because the onset is so severe that they are compelled to seek treatment much earlier than they otherwise would.

The fulminating cases should be treated by an intensive course, as in cholera, with the addition of transfusion if required.

In all such severe cases, be they cholera, food poisoning, or dysentery, I wish to stress the importance of treatment at night. The necessity for this is not so apparent in the minor cases, but in those of the greatest severity, arrangements should be made to give a few doses at night, so that the bowel is never without some inhibiting and bactericidal mixture. In less severe cases it may only be necessary to make the night interval as short as possible, and give one dose the last thing at night and another the first thing in the morning. Only in the severe dysenteries will the necessity for this extend beyond the first night or two.

On the second day eight to ten doses may be given in the twenty-four hours, on the third day six to eight according to the severity of the case. Six to eight doses a day may thereafter be continued for a few days longer, decreased to four daily, finally intermitted for a couple of days, and resumed again. This is to keep up an inhibitory action until the bowel lesions have healed. During this period food may be slowly but gradually increased.

In a few late cases of extreme severity, I have been forced to keep up treatment with more frequent doses for a longer period with an occasional couple of days' intermission.

In cases less intense an hourly dose of the mixture on the first day often suffices, but in all really severe cases it is best to begin with the intensive treatment, reducing the daily doses as before.

Regarding the clinical classification of dysentery, I consider under ten motions in twenty-four hours as mild, ten to twenty as medium, twenty to thirty as severe, and above thirty as very severe.*

The following recent case is worth recording:—

I was called to see a European in his third day of illness. He had had fever and nausea for two days with gradually increasing pain and discomfort in the abdomen, and had been treated by the garden doctor for malaria. When I saw him in the afternoon his temperature was 101.6°F., a basin with much vomit lay alongside the bed, and some eight motions containing first mucus and then mucus and blood had been passed since morning. The stool was watery, only slightly faecal, and contained much mucus and some blood.

On account of the vomiting it was doubtful if the mixture would be retained, but 15 minims of tinctura chloroformi et morphinae co. enabled him to take ten doses that afternoon and evening. The pain in the stomach lessened and he passed a good night. Next morning, and thereafter, his temperature was normal. One semi-solid stool was passed next day with a trace of mucus, and thereafter solid stools. Eight doses were given the second day, six the third, and four thereafter for a week, and he resumed work on the fifth day.

* The exact number of motions is difficult to ascertain in tea-garden practice and in all cases a cigarette tin and a number of small bits of sticks are given to the patient, a bit of stick to be placed in the tin after each motion. This gives as much accuracy as one is likely to obtain in the absence of skilled nursing.

We have next to consider the most anxious cases of all, and these one should scarcely ever find in Europeans, though they are only too frequent in the coolies with whom one has generally to deal.

In this class of case everything is against one: the diet, the lack of nursing, and the lateness of the case. Some of these coolies have been over a week ill, some a fortnight, and some even three weeks.

Let us consider for a moment the condition of the bowel in such cases. There are numerous ulcerated areas, some still covered with a slough, some from which the necrotic portions of mucous membrane have recently separated. Owing to the irritation and inflammation, the bowel is constantly on the move, and cases with fifty motions, or more, are not uncommon. In such cases any medicine we can give is hurried through so rapidly that it has little time to act on the causal organisms, which are, moreover, protected from its action by a layer of mucus or slough.

In addition, an alkaline exudation is poured out by the irritated mucosa, and all these conditions make more difficult the application of an antiseptic and acid treatment, while all except the last hinder the action of such a remedy as the bacteriophage as well.

The reaction of the stools to litmus paper is here a useful guide; if an acid reaction can be obtained improvement occurs much more quickly than if for some time it is found impossible to effect the turn in reaction.

A little further consideration will explain what at first sight may seem difficult to understand, and make a novice doubtful of the value of the treatment if his first experience of it is in such a case.

Even if all the virulent invading organisms be destroyed in such a case, one would still be faced with the healing of large ulcerated areas, bathed in septic exudate, the pabulum of numerous secondary invaders, and healing can only take place very slowly, so that rapid improvement cannot be expected with any treatment.

A proportion of these cases are beyond help, and the damage done before treatment is commenced is so extensive that sooner or later a fatal result inevitably occurs. In such cases no extravagant claims are made for either antiserum or bacteriophage and, though I have often used the former as an auxiliary, I have not, as a rule, seen much benefit therefrom.

The first sign of improvement is a reduction in temperature, and a fall to normal, either quickly, in an earlier case or one of infection by one of the less virulent of the dysentery group of organisms, or later and gradual, in a late case of the more virulent infections. However, in the late-seen and most severe infections of all, those in which the number of stools may be above thirty and as high as sixty in the twenty-four hours, there may be a period of

three days or so after commencing treatment in which the number of motions may actually rise a little in frequency. How much this is due to partial failure of the treatment in the most desperate cases, in other words, inability to render the rapidly-moving bowel exudate acid and antiseptic enough, how much due to the added irritation of cresol on an already intensely irritated and inflamed bowel, and how much simply due to more accurate counting of motions in such grave cases, it is hard to say. It can scarcely be due to irritation from acid, for in such cases it is extremely difficult to render the bowel exudate acid, and I propose, should opportunity occur this season, to increase still further the dose of acid in such cases.

In cases of this description opiates may be of considerable value by lessening pain and irritability; and by lessening the number of motions, enable the acid and antiseptic mixture to act longer upon the affected portion of bowel.

Mixed bacillary and amœbic infection

On first admission every case of dysentery of any severity is treated by the antiseptic method. As the results of amœbic infection are not so rapidly progressive as bacillary, there is still plenty of time for the therapeutic intervention with emetine, should the first treatment fail, or seem only partially effective. Should the opposite line of attack be adopted, and emetine be used first, it may be sometimes impossible successfully to counter the damage done by a virulent bacillary infection during the first few days in which the emetine treatment is being tried out.

There is one fact in the treatment of some of the cases presenting themselves late for treatment which at first I found extremely puzzling. In several such cases the response to acid and sanitol seemed to be delayed beyond five days, and acid and sanitol was suspended, and emetine tried. In many such cases there was a definite reduction in the number of stools within a few days, and this seemed a clear proof that the case must be one of mixed infection. In some cases, however, in spite of the continuance of emetine, the number of stools again increased, and there was a tendency for the temperature to rise, both of which manifestations were checked by a return to the acid and sanitol treatment.

On thinking it over it seemed to me that the decrease in the number of motions was due, in some cases, to the cessation of the super-added irritation of the acid and sanitol just as irrigation will, in some cases of specific urethritis, lead to a continuance of catarrh.

In some such cases I have simply stopped the acid and sanitol, and the same improvement has occurred as in the cases where emetine was used; and in most cases now, before beginning emetine treatment, a couple of days without any treatment is allowed to elapse, and the

reduction in number of stools *after* that time is taken as the measure of response to emetine.

This is one of the points in which it is most difficult to convince one inexperienced in this method of treatment, and the doubt was only resolved in my own case after numerous experiences of the rapid cures achieved in genuine early cases.

Another point in the treatment of these late cases of the more severe type is that, unlike the rapid daily reduction in the number of motions in the earlier cases, the reduction is much more gradual. Quite a common sequence being 15, 15, 14, 13, 12, 12, 10, and so on, the slow reduction being an indication of the very gradual healing of a large ulcerated area.

These difficulties only occur in late cases; it may, I think, be taken as axiomatic that green sloughs are *not* passed in the first few days of the attack, and that any case in which such appearances are present in the stools is in all probability nearly a week old, if not older. It is only the coolie who is so reluctant to seek early treatment, and my experience with the few Europeans, whom I have so far had occasion to treat by this method, has been uniformly favourable.

My practice now is to continue the acid and sanitol treatment in late and severe cases for periods of ten days or a fortnight, beginning with more numerous doses and gradually working down to six doses daily, and finally to four. At the end of this I often discontinue the treatment for a couple of days, and then resume again for three days, and so on, in alternate periods of treatment and intermission, until the patient is cured. In cases in which mixed infection is thought to be possibly present, the periods of intermission are often used for emetine injections.

McCay (1932) gave a mortality of 8.2 per cent for 231 cases of bacillary dysentery treated in the Presidency Hospital, Calcutta. His greatest mortality occurred in children.

In a series of 320 cases in one large garden treated under tea-garden conditions, during two epidemic years, and minus all the refinements of food and nursing, there were 34 deaths, making a mortality rate of 10.6 per cent, and these deaths occurred entirely in children and late cases. Though these were not all bacillary cases, certainly the majority were, the diagnosis being made clinically and therapeutically. Any gain in mortality figures obtained in this way is more than offset by the hopeless condition in which some patients were admitted. Included in these figures are absconders who, sick unto death, struggled back to the garden they had left, to die within a few days of admission to hospital.

Regarding the likelihood of relapse after this form of treatment, I have not seen a single relapse in a case admitted early. I have no

accurate figures for the relapse rate in later cases, but it is comparatively small.

Criticisms of and difficulties of this treatment

(1) The danger of producing acidosis; this, which for years deterred me from using any but minute doses of acid, is, I find with increasing experience, scarcely, if at all, evident.

(2) The effect of cresol on the kidneys; Ganguly (1925) drew attention to the fact that few cases of uræmia occurred when cholera was treated by izal, in accordance with my first cresol method but using a different brand of cresol, but he expressed surprise at this.

I can only say that since treating cases of cholera in this manner, I have not seen any cases of uræmia, though previously I came across them fairly frequently.

In dysentery, where the treatment with acid and sanitol has been continued for a long time in late-admission cases, I have twice come across children with œdema of the legs and slight albuminuria, but this has cleared up in both cases on stopping treatment by sanitol, and giving acid only. On the other hand, some œdema of the feet is very common in all cases of late dysentery admitted to hospital, and it may be accompanied by slight albuminuria as well, so that it is not at all certain that the transient albuminuria was the result of the drug.

(3) That the mixture is difficult to take; this is not particularly the case, and anyone who wishes to compare it with the essential-oil mixture will, I think, find that it is much less nauseating. I have recently had two Europeans upon this mixture, and both found little difficulty in taking it, but it is, of course, more difficult to take than the bacteriophage.

(4) Difficulty in administering to young children; this is a very real difficulty, but it is one which applies to nearly every medicine administered to children. Administration in small quantities, and holding the nose and closing the mouth until swallowing has taken place often suffices. Children of even under a year have been so treated, though I fancy the small amounts administered could do little more than facilitate the working of the *vis medicatrix naturæ*.

The difficulty in administration of medicine, the late date at which Indian children are often brought for treatment, and the delicacy of the bowel mucosa, all probably contribute to the greater mortality in such cases.

In conclusion let me emphasize that this method of treatment is polyvalent, and applicable to all the bacillary intestinal infections, with perhaps two exceptions.

The first of these is *B. pyocyaneus* infection, in which, on other grounds, I am doubtful of the antiseptic value of the cresol group. For such, probably acid alone would be as useful as acid and sanitol.

OBSERVATIONS ON THE NORMAL DIET- ARY OF INFANTS AND CHILDREN IN VIZAGAPATAM

By M. V. RADHAKRISHNA RAO, M.B., B.S.

Research Fellow, Andhra University

(From the Out-Patient Department, King George Hospital, Vizagapatam)

COOMAR (1888), Bose (1890), Nandi (1931), Mukherji (1922), Green-Armytage (1926) and Green-Armytage and Vere Hodge (1929), among others, have pointed out that the irregularities in the feeding of children are associated to a great extent with the causation of infantile biliary cirrhosis. These observers, especially Coomar, laid great stress on the importance of studying the hygienic and dietetic conditions in children suffering from infantile biliary cirrhosis to elucidate the cause of the disease. Before proceeding with the study of this subject, the normal dietary of infants and children in Vizagapatam was carefully investigated and is recorded in this paper, with a view to denoting the deviations from the normal in the dietary of children suffering from infantile biliary cirrhosis.

The material in this paper consists of an analysis of the case-notes of 1,100 children (below 5 years) carefully examined in the medical out-patient department of the King George Hospital, Vizagapatam. Detailed notes were taken about the diet of the children from the parents or guardians accompanying them. The children are roughly classified into different classes according to the status of the parents or guardians.

(Continued from previous page)

The second class of case is one of a rare and obstinate variety of dysentery, which on culture has given large numbers of lactose-fermenting streptococci in almost pure culture. Whether this is identical with the organism isolated by Bergen, or merely a secondary infection, I am unable to say. In the few cases in which I have found it, it seemed to me that better results were obtained from slightly increased doses of sanitol only, but, so far, this is an impression lacking absolute conviction.

I believe those who may decide to try this method of treatment will have no reason to regret it.

Most of the children belonged to the Hindu community as may be seen from the analysis below :—

Religion	Number
Hindus ..	986
Christians ..	30
Anglo-Indians ..	16
Mohammedans ..	67
Martwaris ..	1

The age distribution of the 1,100 children is given below. Most of the children examined were under 3 years :—

Age in years	Number
Under 1 year ..	363
1-2 years ..	303
2-3 " ..	248
3-4 " ..	115
4-5 " ..	71

The table shows the results of the investigation into the mode of feeding in these children examined. It will be seen that breast-feeding of the children is the invariable rule among all the classes, except in a few cases (25 in this series) in which it was contra-indicated on account of the mother's poor health. The rules laid down regarding the breast-feeding of children (e.g., the quantity at each feed, and the interval between the feeds) are never followed, especially by poor and lower middle-class mothers. The women of the poor class suckle their children usually till the end of the second year, but sometimes they do so till the end of the third or fourth year. These women belong to the labouring class and are fairly healthy. Their diet is very poor (especially in vitamins) and consists of rice and *cholan*, with little or no vegetables and excess of chillies; meat, fish, milk or milk-products are only taken occasionally. In the middle and rich classes the children are generally weaned at the end of the first year.

The custom of feeding children by a wet nurse is not very prevalent. In a few cases, in which the mother died after the birth of the child, this method was resorted to, and in all these instances the wet nurse happened to be from the same family.

Though goat's milk very nearly approaches human milk in composition and is easily digested, the idea of feeding children with this milk is not popular. Only in two cases was goat's milk given in addition to breast-milk.

Breast-milk is frequently supplemented with cow's milk. Buffalo-milk is generally not used in the dietary of infants. The artificial feeding of infants with cow's milk is highly unsatisfactory among all the classes, especially the poor and lower middle classes. The milk is

invariably boiled and diluted before use and the cream is generally removed. In the poor and lower middle classes the milk is diluted according to the whims of the ignorant mothers and often the diluted cow's milk is continued even after the age of one year; in most cases, the diluted cow's milk is given from birth to supplement breast-milk. The addition of sugar to

the diluted milk is neither constant, nor proportional. The children in these classes are either over fed or under fed and gastro-intestinal disturbances are very common. Even the mothers belonging to the upper middle and rich classes, especially the Hindus, are equally ignorant about the proper methods of 'humanizing' cow-milk before it is given to the infants, and very

		TOTALS ..	363	488	36	887

little attention is paid to the general hygiene necessary in artificial feeding.

The selection and the use of tinned and patent milk-foods varies in the different classes. Nestle's sweetened condensed milk is the favourite form of tinned milk-food given to the infants of the poor and lower middle classes. Horlick's malted milk and Glaxo (full cream) are generally used by the upper middle and rich classes. These foods are given instead of cow's milk to supplement breast-milk. In a few cases (14 in this series) they are given from birth. In selecting these foods, the choice is generally made by the parents, or on the advice of friends or relatives, irrespective of the requirements of the baby at a particular period, and medical advice is only sought for when the several preparations on the market are tried and found unsuitable to the baby. The Anglo-Indian and some of the Christian mothers are more careful in this respect. Their children are generally healthier and stronger than the children belonging to the other communities.

In most cases starchy food in the shape of rice is given from the end of the first year. Children of the poor class are often given rice or rice-congee from the end of the 6th or 7th month. At first they are fed on rice with pepper-water (*rasam*) only, but afterwards also on small quantities of all the foods prepared for the adult members of the family. Such additions are made gradually. Rice is the staple article of diet in all classes and in the vegetarian families there is an excess of carbohydrate in the diet. Though the children belonging to the poor and lower middle classes are mostly non-vegetarians, yet meat and fish are given to them only occasionally.

When once the child is given rice-diet regularly, cow's milk is generally stopped, except in some of the middle and rich class children, who are given small quantities of milk in coffee or ovaltine. In the poor class breast-feeding is continued, sometimes up to the end of the fourth year, even after starting the children on regular rice-diet.

Fruit juices are not generally given to the infants in all the classes, unless they are recommended by a doctor.

Summary

Observations on the normal dietary of infants and children in Vizagapatam, based on a careful investigation of 1,100 children in the medical out-patient department of the King George Hospital, are recorded in this paper. It is observed that :—

(1) the infants are invariably fed on breast-milk except in the few instances in which it was stopped on account of the poor health of the mother;

(2) the artificial feeding of children is very unsatisfactory, especially in the poor and lower middle classes; and

(3) starchy foods are given very early to the children by the poor class mothers.

Acknowledgment

I wish to express my thanks to Rao Bahadur Dr. T. S. Tirumurti, Professor of Pathology, Medical College, Vizagapatam, under whose direction this investigation was commenced, and to the Superintendent, King George Hospital, Vizagapatam, for giving me every facility in the out-patient department of the hospital to carry out this investigation.

A Mirror of Hospital Practice

A FATAL CASE OF CHRONIC INTERSTITIAL NEPHRITIS WITH VERY HIGH BLOOD UREA

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)
 LIEUTENANT-COLONEL, I.M.S.

and

R. N. CHOUDHURY, M.B. (Cal.)

(From the Carmichael Hospital for Tropical Diseases, School of Tropical Medicine, Calcutta)

M. K., a medium-built, anæmic, vegetarian, Punjabi Hindu male, aged 43 years, was admitted into the Carmichael Hospital for Tropical Diseases with the history of persistent dyspnoea for the past three weeks and hiccough for the last 12 days. He also complained of scanty urine, giddiness, loss of memory and insomnia. He was said to have had high blood pressure. About a year ago he suffered from dysentery and influenza; there was no history of syphilis.

On admission the patient had orthopnoea, intermittent hiccough, restlessness, subnormal temperature, oedema of the feet and moderate ascites. He had pyorrhoea, and his tongue was coated and somewhat dry. His face was pale and the veins of his neck were engorged. There was congestion of the bases of both the lungs. The apex beat was in the 6th interspace $1\frac{1}{2}$ inches outside the left mid-clavicular line. The first sound was muffled, and the aortic second sound was accentuated. The pulse rate ranged between 90 and 110 per minute. The blood pressure was systolic 200 Hg. mm., diastolic 125 Hg. mm. and the radial artery was thickened. The liver was enlarged and tender, and pulsation of its lower border synchronously with the heart beat could be distinctly felt.

The urinary output ranged between 10 to 20 ounces per diem. The urine contained 0.38 per cent of albumin with a few hyaline casts; a moderate amount of urobilin and indican and a fair number of pus cells were present; a few red blood corpuscles and calcium oxalate crystals, and numerous bacteria were also found. On examination of the stools no protozoa except *Blastocystis hominis* were detected and on plating *Salmonella morgani* was isolated. *Trichostrongylus* ova were found in the stool.

The case was diagnosed as one of chronic interstitial nephritis with dilatation and failing of the heart. He was ordered blue pill and magnesium sulphate and was also given over three drachms of digifortis in three days followed by diuretin, but with no beneficial results. The hicough continued unabated, the urine secretion was not increased and the patient could not get a wink of sleep. On the last day, an intravenous injection of glucose with strophanthin was given and leeches were applied over the liver region without any effect. The patient remained conscious though very restless till his death on the fifth day after admission.

The interest of this case lies in the fact that an examination of the blood 12 hours before death showed 220 mgm. per 100 c.cm. of urea, the normal urea in Indians being 15 to 20 mgm. The patient did not get any convulsions with this high urea content, was quite conscious and notwithstanding it lived for more than twelve hours.

A CASE OF APLASTIC ANÆMIA

By P. N. MITRA, M.B., D.T.M.

Teacher of Pathology, Berry White Medical School, Dibrugarh

THE patient J., a Hindu male, aged 38, married, was working as a ward servant and was admitted for treatment of giddiness, of one week's duration.

23rd August. On admission his pulse was 100 and respiration 28 per minute, and temperature 98°F. There was nothing particular about his family history, personal history and previous illnesses. About a week before admission he scratched his right ear with a match stick and lost about half an ounce of blood. He also took a dose of oil of chenopodium and felt weak and giddy, after the purging which followed the drug. He was however working up to the day of admission.

Physical examination. Of average physique; extremely anæmic; no jaundice, no glandular enlargement.

Gums—spongy; tongue—dry and coated; spleen and liver—not palpable below the costal margin. Soft systolic murmur present in the pulmonary area. There was a slight cough and there were a few moist sounds in the left side of the chest.

Stool—no cysts seen; ova of round-worm present.

Urine—nothing abnormal.

Blood—no malaria parasites seen.

Hæmoglobin—15 per cent (Tallquist).

Red corpuscles—735,000 per c.mm.

White corpuscles—2,812 per c.mm.

Polymorphonuclears—26.0 per cent.

Lymphocytes—61.6 per cent.

Large mononuclears—10.0 per cent.

Myelocytes—2.0 per cent.

Eosinophiles—0.4 per cent.

1st September. Fractional gastric contents test with a Ryle's tube, after an alcoholic treatment, showed no free hydrochloric acid.

4th September. Van den Bergh test—direct and indirect negative.

6th September. 'Hepatex' P. A. F. 5 c.cm. injected intravenously.

8th September. Red corpuscles, 535,000 per c.mm.
White corpuscles, 2,150 per c.mm.
Polymorphonuclears, 40.0 per cent.
Lymphocytes, 58.4 per cent.
Large mononuclears, 1.6 per cent.

Arneth count

I	II	III	IV	V
40	38	17	5	0

Three normoblasts were seen while counting 250 white cells; a few polychromasic red cells were seen. The red cells showed slight anisocytosis and almost no poikilocytosis.

The patient ran an irregular temperature while in hospital and died on the 8th September. No post-mortem examination was allowed.

Discussion.—The only disease with which this can be confused is acute infectious anæmia, where hæmolytic occurs. The man was however working up to the day of his admission; the blood count was extremely low and the usual signs of blood regeneration were absent on the first count. There was also an absence of anisocytosis and poikilocytosis and the van den Bergh test was negative, there was no evidence of increased blood destruction. The total counts were still lower on the day of the second count but a diagnostic difficulty is introduced by the presence of a higher percentage of neutrophils in the differential count, shift of the Arneth index to the left and the presence of a few normoblasts and polychromasic red cells. The normoblasts and polychromasia are probably explained by the injection of 'Hepatex' on the 6th September. Pincy (1927) says that 'the greater part of the marrow of all the bones is aplastic but some areas of practically normal marrow may remain'. Liver has the property of producing even in a normal person a condition like erythræmia (Ordway and Gorham, 1930) so probably the liver extract stimulated the remnants of healthy marrow to produce the reticulocytes, polychromasic cells and normoblasts. The change in the neutrophils was probably due to sepsis, which was the cause of the fever and which was not definitely localized. Unfortunately the blood was not cultured.

Colonel J. L. Sen, I.M.S., the superintendent of the School, has kindly permitted me to publish these notes.

[Note.—In view of the complete 'achlorhydria' and the left-handed shift in the Arneth count, and in the absence of any information regarding the reticulocyte count or the red-cell diameters, we feel that the diagnosis in this case was not based on very strong evidence.—EDITOR, I. M. G.]

TREATMENT OF MYIASIS

By B. R. GARG, L.M.P.

Muzaffarnagar

J. L., HINDU MALE, aged 65, consulted me for a putrid sore on the back of the hand, wrist and forearm. The whole of the lower arm from the tips of the fingers up to the elbow was cedematous and swollen. The skin had peeled off at several spots and the wound looked gangrenous, it was full of fly larvæ, which were burrowing deeply into the muscles.

The wound was washed well with a lotion of crysol 1 in 20; undiluted crysol was put into it and it was covered with a dressing moistened with a lotion of crysol 1 in 20. Next day when the dressing was removed more than 100 dead larvæ were disclosed; the condition of the wound was better and pain was much less than before. The same treatment was continued and all the larvæ disappeared by the fifth day. Crysol 1 in 20 was continued as a dressing for three weeks, by which time the wound was healed.

2. Y. S., Hindu male, aged 27, came for treatment and myiasis of the nasal cavity and the soft palate was discovered. His palate had already perforated. I first tried chloroform, and there were no signs of improvement after twenty-four hours, so his nasal cavity was irrigated with a crysol solution 1 in 20 and crysol was applied to the wound in the soft palate. He made rapid progress, ejecting every day a large number of dead larvæ, and was completely cured within twelve days.

3. L. S., Hindu boy, aged 12 years, had a wound in the external ear. The boy had suffered from suppuration of the ear for a number of months; this was treated with hydrogen peroxide which cleaned it up temporarily. But having neglected the ear for some time it became infected with fly larvæ. The cavity was syringed with crysol 1 in 20 twice daily, and crysol 1 in 4 in glycerine was dropped into the ear and the boy was cured within a week.

It is probable that any of the coal-tar disinfectants would be as effective as crysol.

[Note.—We are informed that crysol is a disinfectant prepared by a firm of chemical manufacturers in Delhi.—EDITOR, I. M. G.]

NAGA SORE IN RAJKOT (KATHIAWAR)

By T. H. TRIVEDI, D.T.M. (Cal.)

In Charge West Hospital Laboratory, Rajkot

A boy presented himself for treatment at the above hospital with ulcers on his legs that had the typical appearance of Naga sores.

The boy gave a history that the lesions began as small pustules which ruptured and afterwards had spread until the condition shown in the photographs was presented.

Diagnosis was confirmed by finding fusiform bacilli and spirochaetes in the discharge.

Treatment.—Under the treatment recommended by Lieutenant-Colonel Acton, at the Calcutta School of Tropical Medicine, these ulcers healed satisfactorily.

The treatment consisted of syringing with hydrogen peroxide to remove the sloughs followed by a bath of weak potassium permanganate solution for half an hour, and a dressing of hypertonic saline solution. This treatment was performed daily until healthy granulation tissue had formed when a dressing of boro-vaseline was employed.

Inquiry revealed the fact that this boy was born in Rajkot, was an inmate of the Rajkot orphanage, and never had been out of the district. As far as the writer is aware this condition has never before been recorded in this part

of India, it usually being looked upon as only endemic in the more humid parts of the country.

I wish to thank Major Vance, I.M.S., and the chief medical officer, Western India States hospital, for permission to publish these notes.

Indian Medical Gazette

MARCH

THE THERAPEUTICS OF MALARIA

THE Third General Report of the Malaria Commission of the Health Organization of the League of Nations, on the therapeutics of malaria, is a document of such first class importance that we need make no excuses for reprinting considerable portions of it in our Current Topics section this month. The whole report covers over a hundred pages of the *Quarterly Bulletin of the Health Organization*,* and it should be read *in extenso* by all public-health officers in malarious countries as well as by all those who make any special study of the mass or individual treatment of malaria.

The therapeutics of malaria is such a many-sided subject that it would have been impossible to do full justice to all its aspects in a report even of this length. The economic aspect, the most important from the point of view of India, has not been entirely neglected, but has not received the attention we should have expected; this aspect, which is inevitably associated with the total-cinchona-alkaloids problem, we will leave for later discussion.

The principal impression which the reading of this report gives is that our knowledge on every aspect of the problem of the treatment of malaria is most surprisingly indefinite, and it can be said that the principal thing the authors have achieved is an accurate definition of the limitations of this knowledge.

The last chapter, the summary and conclusions, of this report is a masterpiece of clarity and precision. One of the principal points made is that there is no 'standard treatment for malaria'; a form of treatment that is adequate for one species of malarial parasite is not adequate for another species, or even for another strain of the same species; the course of treatment that should be given for a primary attack is not necessarily the course that should be given for a relapse, or a recurrence; and the tactics that one would adopt to deal with malaria in one affected population might be quite wrong if applied in another. That is to say the treatment of malaria is far from a simple problem, and it cannot be reduced to the matter of a fool-proof formula, or even of a number of formulæ. The commission are not prepared to make any specific recommendations; they lay down guiding principles only, and leave it to

each country and district to work out the solution to its own special problem. This, it might be said, is not very helpful; but in actual fact it is, and a reference to the report, or even to the extracts that we have given in this number, should satisfy the reader on this point.

The aims of treatment of malaria can be considered under five separate headings; each of these aims is quite distinct from the others, and much confused thinking (and writing) would be avoided if this could always be remembered. We will consider these one by one.

(a) *The destruction of the sporozoite infected by the mosquito before it establishes itself in the body cells of the host; that is to say, 'true causal prophylaxis'.*

At the present time there is no drug, given in non-toxic doses, that will achieve this. For many years it has been recognized that quinine was useless for this purpose, and evidence has recently been produced to show that atebirin also fails; with plasmochin in truly toxic doses an apparent success has been achieved, but failures have been reported with doses as large as 0.06 gramme per day, a dose that will cause symptoms in quite an appreciable percentage of the people who take it.

(b) *The maintenance of the infection at a sub-clinical level; that is to say, 'clinical prophylaxis'.*

This can only be achieved by continuous dosage over a long period; for this the commission recommend quinine in six-grain (0.4 gramme) daily doses to be taken the whole time the subject is exposed to infection and for some months afterwards. This recommendation is based on an extensive clinical trial with people who have acquired a degree of immunity. In the controlled experiments with non-immune subjects, it was found that a dose of five grains of quinine daily did not prevent a clinical attack of malaria, but caused a modification of this attack. On the other hand they report parallel experiments with atebirin which show that a dose of one grain daily will maintain clinical prophylaxis, but this is not, any more than quinine, a true prophylactic because when the drug is discontinued the patient will eventually get an attack of malaria. The reason that they do not recommend atebirin instead of quinine in this capacity is apparently because there is as yet no evidence to show that the former is harmless when taken for long periods, and because it is liable to cause, even in this small dose, a slight discoloration of the skin and conjunctivæ. Time will very shortly supply this information, as most people find this daily dosage with quinine very trying and many will undoubtedly substitute atebirin. Plasmochin is not recommended as, to be effective, it has to be taken in doses bordering on the toxic limit; this it would be unwise to continue for long periods.

*The fact that we are only now commenting on this report seems to call for some explanation. Our copy of the number of the *Quarterly Bulletin* in which this appeared went astray in the post; this we only realized when we received the next number.

(c) *Destruction of the parasites in the fully-developed early schizogony cycle; that is to say, the treatment of the malarial attack:*

Here the commission are rather more prepared to be definite about what must not be done than about what must be done. What one must not do is to give a very vigorous and long-continued course of treatment in an attempt to deliver a knock-out blow to the infection at this stage. The reason why this must not be attempted is because it cannot be done. A moderate dose given over a short period will produce as good an effect as a large dose over a longer period; the excess is not only wasted but, to continue our metaphor, glances off and is liable to knock out the resistance of the patient. This is perhaps one of the most important points that the commission makes; they emphasize that no drug will cure malaria unaided and that we always depend to a certain extent on the natural resistance of the patient, and that if we can tide the patient over this first attack with as little assistance as possible, the more will his natural resistance be raised and the better will he be able to deal with relapses or recurrences. Opinion has been for some time tending in this direction and the support given to it in this report should go a long way to end the 'big stick' methods that have been adopted in the treatment of malaria. The commission will not accept the responsibility of recommending to the exclusion of the other either atabrin or quinine for the treatment of the attack of benign tertian malaria; both they say are equally good. They do, however, give definite preference to atabrin* in the treatment of malignant tertian, but not of course to the complete exclusion of quinine, which, they admit, is a very valuable drug even in this infection. But they are quite definite in their assertion that on no account should the treatment of the primary attack be prolonged for more than seven days, and they appear to favour a five-day course. Again they do not think that plasmochin has any place in the treatment of the disease at this stage.

(d) *The destruction of the parasite in its latent stage; that is to say the prevention of relapses and recurrences.*

The commission are particularly discouraging in their recommendations here. They say that there is no drug, be it given in doses ever so large, that will prevent a relapse of benign tertian malaria with certainty and they take the defeatist attitude that it is therefore no use trying. Their recommendation practically amounts to treating the relapses and recurrences when they arise. With regard to malignant tertian they suggest that, as it does not appear

to be so difficult to bring about sterilization, this might be attempted. Except that they say that this preventive course should not be commenced until at least a week has elapsed since the completion of the treatment of the attack, their suggestions as to how this sterilization is to be achieved are not very explicit, nor do they seem to make it clear how the procedure differs radically from that adopted with regard to benign tertian or quartan malaria. We have for this reason given the summary of this subsection in full:

In support of the suggestion that a better result will be obtained, if, when quinine has been given in the first attack atabrin be given in the relapse and *vice versa*, no evidence is quoted; it sounds a reasonable suggestion but one would like to know that it was not a guess.

They do not consider that the evidence at present available is sufficient to justify the conclusion that plasmochin alone, or plasmochin plus quinine, is better than quinine alone, as a relapse-preventing drug.

(c) *The destruction of gametocytes, to eliminate the source of infection of mosquitoes, as an antimalarial measure in a community.*

This the commission appear to consider the only legitimate use for plasmochin; they suggest that it be given twice a week. In this connection they draw attention to the fact that recent experience has shown that there is no justification for the assumption that treatment tends to raise the number of gametocytes, or that these are evidence of increased immunity; on the contrary, it is pointed out that the higher the immunity the lower the number of gametocytes. There are fewer gametocytes in relapses than in the primary attack, and they are many times more common in young children with their low immunity than in adults. The moral of this is that if anti-gametocyte measures are to be adopted great care must be taken that all children are treated, as missing one child may be of far greater importance than missing a score of adults.

The foregoing summarizes the recommendations of the commission but there are many other points raised that will certainly stimulate discussion. A very interesting observation, to which they have drawn particular attention, is the appearance of late relapses, or 'recurrences' as they call them for convenience. These occur between the seventh and tenth months after the primary attack and in benign tertian are more frequent than the early 'relapses' that occur after ten days but within two months. They do not give any explanation of this phenomenon. [One that suggests itself is that in the first attack the 'immunity' of the patient, induced by the attack and perhaps aided by the drug given, destroys most of the parasites in the blood in that attack, and is sufficient to keep the infection at a sub-clinical level so that the next attack, which would normally

* We find this difficult to understand in India where quinine acts so effectively in this infection; one hopes that the claim is not dependent on James' few observations with the quinine-resistant Rome strain of *P. falciparum*.

occur when the parasites had multiplied sufficiently, will abort, but the immunity of the patient is further raised during this process and is now sufficient to keep the infection at its latent level for some considerable time. It is probable that this immunity is not permanent, and at the end of nine months has fallen low enough to allow the malarial parasites to multiply and cause another attack. This 'recurrence' will probably raise the immunity to a much higher level. But is there any guarantee that even this has completely destroyed the malarial parasites and that the malaria will not recur in these cases after perhaps 18 months or an even longer interval on this occasion? At this early date it can scarcely be claimed that this assumption is based on experience.] These 'recurrences' have not been recognized clinically, as such, in tropical countries; this, it will be affirmed, is because they have always been labelled as fresh attacks. This explanation would only hold if they were rare, and one is driven to the conclusion that they are mainly phenomena of the primary attack. Sinton and his colleagues selected two months, partly for convenience but mainly from the practical experience that relapses or recurrences seldom occurred after this date; they may not have followed up their patients individually, but, as their patients were soldiers, the fact would certainly have come to their notice had many relapses occurred at a later date; it therefore seems quite probable that in this class of patient these late recurrences are rare, and that it is justifiable to ignore them in testing the *relative* relapse-preventing properties of a drug or combination of drugs.

A criticism that we feel we must make is that throughout the whole report the extreme caution with which the observations of very reliable workers in malarious countries are accepted appears in very marked contrast to the ready accord given to dogmatic conclusions apparently based on a few controlled experiments in England and other non-malarious countries. It must not be thought that we underestimate the importance of these controlled, pseudo-natural experiments. They have provided us with facts and figures regarding the course of the disease and its therapeutics that otherwise it would have been impossible to obtain and they have not only given a badly-needed stimulus to the whole subject of malaria therapeutics but have led to a tremendous advance in our knowledge of the whole subject. From these experiments we can make deductions regarding the relative action of drugs under field conditions, but it must be remembered that at the best they are only one stage removed from laboratory experiments and that conclusions based on them are only directly applicable to one particular set of conditions, namely, that of the well-fed, bodily-healthy European spending a short time in a malarious country. This particular aspect of the problem represents

a small fraction of the whole malaria problem that has to be faced.

It is admittedly exceptional for conditions to occur which allow treatment experiments to be conducted actually in tropical countries, but now and then such opportunities do arise. Acton's experiments in 1919 at Dagshai and the similar experiments at Kasauli carried on by Sinton and his colleagues are examples; these experiments are admittedly open to certain criticisms and the results obtained are not capable of universal application, but at least they represented an actual problem and moreover a problem which now appears to have been solved; the 'relapsing' soldier has become so rare that this work has had to be given up. The general impression, which of course may be wrong, is that this has been brought about by the use of plasmochin *plus* quinine.

Sinton and Bird's experiment with this combination, in which they had only three relapses in thirty-six cases as compared with the usual relapse rate of 70 per cent that they had been getting with quinine alone, was very significant from a mathematical standpoint; this work was mentioned, but not taken into consideration in drawing the conclusion, apparently because the cases were not followed up for a sufficiently long time to exclude possible 'recurrences', which we have no reason to suppose are common in patients of this class.

The commission claim that it is paradoxical to assume that the giving of two drugs, one of which is not a specific and does not combine with the other to form a new compound in the stomach, may effect a higher cure rate than the giving of the specific alone. With this we cannot agree; there are many examples in therapeutics of the combined action of two drugs differing from the sum of their separate actions. Whether any benefit is derived from combining the use of alkalies and quinine we are not prepared to affirm, but it is certainly not paradoxical to assume the possibility.

The suggestion that moderation should be exercised in treating the primary attack and the early relapses, and that the less treatment that is given without endangering the life (or, one presumes, sacrificing the comfort) of the patient, the greater will be the resistance to future relapses, or even fresh infections, is, we feel sure, very sound, and as we have said one of the most important recommendations of the commission, but even this suggestion will not bear following to its logical conclusion. For it would mean that the indigenous inhabitants of malarious countries, many of whom have little or no quinine all their lives, should be healthy, malaria-resistant people, the weaklings having all been killed off and the rest having acquired a natural immunity. This is not the usual picture of malaria-ridden populations, though it may be true of a few. There must be some other factor. Perhaps we are wasting our time over this treatment problem and possibly it is

this other factor that we should be looking for! In any case we feel certain that experimentation will have to be carried beyond the walls of mental hospitals in Europe and America, if we

are to find the solution to the problem of the relief of malaria-stricken populations, those of the Roman Campagna and of Bengal, for example.

Special Article

FRACTURE EQUIPMENT: WITH NOTES ON ITS USE

By H. R. RISHWORTH, F.R.C.S. (Eng.)

District Medical Officer, G. I. P. Railway, Byculla, and Hony. Visiting Surgeon, St. George's Hospital, Bombay

Part II

AMBULATORY APPLIANCES

BONES of the lower limb, like those of the spinal column, require longer periods of abstention from full functional use after fracture than other bones of the body. In addition to the other functions of bone they have to carry the weight of the body during a great part of the day. In the case of the femur, particularly if the line of fracture has been oblique, continuous weight-bearing before the callus has sufficiently consolidated, will result in a gradual slide of the fragments. The ultimate shortening may be $\frac{1}{2}$ to $\frac{3}{4}$ inches more than when the patient left his bed. Apart from this, if the patient can get about without allowing the weight to bear on the broken bone, not only do we diminish the burden of attendance and nursing at an early stage, but we hasten healing by improving the patient's circulation and general condition. We can go even further than this; by suitable walking appliances it is possible to treat patients with lower-limb fractures as out-patients, or allow them to return to their head-quarter stations for considerable periods. Finally, the lot of those unfortunate patients with open fractures which have developed a low-grade osteomyelitis can be considerably ameliorated and the nutrition of the parts improved by getting them out of bed. Sinuses tend to heal and the tenderness of the callus diminishes more rapidly than when the patient is confined to bed. The economic gain is considerable.

Two such appliances have been included in the standard scale recommended by me in part I of this paper (p. 35). These are shown in figures 22 to 26, with full details for making them. Figure 25 is an outline drawing showing the method of application with plaster of a walking stirrup iron for lesions below the knee. The vertical rods of the stirrup should be in the axis of the limb. If they lie with an angle to the axis opening either forwards or backwards the patient will not be able to walk in comfort. The upper end of the plaster should be well moulded under the tuberosities of the tibia and the head of the fibula. It is advisable to use a wool bandage under the

plaster until experience has been gained in the use of plaster. A non-padded plaster cast is lighter and maintains the fragments in better fixation. The loop of the iron is adjusted about $1\frac{1}{2}$ to 2 inches below the sole of the foot. The bandage should be crossed around the vertical supports, as shown in the diagram, to ensure fixation. If this is not done a back and forth looseness soon develops. Such a plaster properly applied *will last for weeks* while the patient gets about. The position of the fragments can be checked by x-ray through the plaster. If the position is bad the splint should be reapplied.

All patients with fractures of the femur should be made to use a walking caliper up to a period of 4 to 6 months from the date of injury. An adjustable caliper is shown on page 153. A thigh strap and an ankle strap pass through the loops provided on the side rods. The ankle strap should be firm so as to prevent the limbs of the caliper from springing apart and allowing the lugs to escape from the holes in the heel of the boot. Indians who do not wear boots should be provided with wooden sandals the soles of which are $1\frac{1}{2}$ inches thick. These may be bandaged to the foot. Some patients learn to use the caliper in a very short time. Others may require half-an-hour's lesson with two attendants, twice daily for a week. I had an old lady who twice fractured her femur at an interval of two years. On both occasions she used this caliper and could easily walk to church on it, a distance of half a mile, unaided, besides doing her usual constitutional each day. The patient learns to sit on the inner part of the ring at each step, using the tuber ischii to bear the weight of the body while the sound leg is swung forward. A shoulder strap passing over the sound side may be necessary to keep the ring up. It can be fashioned from stout calico. Some patients prefer to hold the outer side of the ring with the hand of the injured side.

During the past six months I have used the walking stirrup iron in the following fractures. Severe Pott's fracture, fracture of the fibula, fractures of the metatarsal bones, fracture of the internal malleolus, fracture of both bones of the leg, and also in the case of a patient, with an old open fracture of the tibia and a sinus, who had been confined to bed for several months before I saw him. In all these cases the patients were allowed up and about the day after the application of the plaster.

BRAUN'S SPLINT

Originally devised as a fixation apparatus for the ambulatory treatment of tuberculous knees, Thomas' splint depends for its success as a fracture appliance on two factors, namely support and extension. If both these factors are properly exercised it has no rival as an ambulatory appliance for transport in the case of fractures of long bones. No single appliance in fracture equipment has stood the test of war and post-war experience so successfully in this respect.

Support is obtained on the sling principle by strips of material passed over and attached to the side rods. Extension is less simple. The traction rod from the foot is passed over or fixed to the cross rod at the end of the splint. The force applied is thus transmitted to the padded ring which abuts against the tuber ischii. The stronger the force applied to the end of the splint the greater the pressure of the ring on the tuber so that the limb is kept taut between these two points. Reduced to its simplest analogy the limb takes the part of a bow-string while the splint is the bow. If this analogy is disturbed in any way the principles of the splint are interfered with, so far as extension is concerned, and it loses some of its value.

I am aware that this might sound terrible heresy to those who are devoted to Thomas' splint under any circumstances. However, consider the question further; in those cases where Thomas' splint is used as a permanent appliance in the treatment of fractures of the long bones, we often see the traction cord carried beyond the end of the splint without attachment to it, and run over a pulley on an independent support or Balkan appliance. The immediate effect of this is to abandon the intrinsic extension feature of the appliance and to use it merely as a means of support. If the traction cord is not allowed to act on the end of the splint no counter pressure reaches the tuber and the analogy of the bow is lost. In all these cases the manipulator finds that the foot of the bed must be raised to provide counter extension by the weight of the body.

Used merely as a means of support without intrinsic extension Thomas' splint has certain disadvantages. If the tuber ischii is not used as a pressure point the large padded ring is an encumbrance. It interferes with the use of the bottle and the bed pan and in hot weather is insanitary owing to the leather covering. Its circular shape also allows rotation of the appliance in its long axis. A half-ring type has been evolved, but does not entirely meet these objections. Illustrations in textbooks and journals show various devices to overcome the rocking of the splint on its long axis. The patient may constantly require adjustment of the splint and rest is impaired. The nurse or attendant needs to be possessed of unusual 'splint instinct' to make a fidgety patient comfortable. Suspension

cords from the ring and from the side rods are sometimes carried over pulleys attached to the suspension beam overhead. This increases the complexity of the apparatus. In some cases the end of the splint is secured to the vertical support of the Balkan beam at the foot of the bed. This is mechanically unsound as it fixes only one end of a long splint, and since the fixation is in the line of the long axis of the splint it does not completely control the rocking movement. In cases where direct extension from the knee is used by means of tongs or calipers an additional knee-flexion piece is essential, if the leg is to be removed from the line of traction. On the other hand, if extension is made by means of adhesive of any kind, the knee must be kept straight with the danger of stiffness of that joint or relaxation of the ligaments. Movements of the knee cannot easily be carried out without interference with the extension. If this splint is used for the treatment of fractures below the knee joint, the knee must perforce be kept extended. This is an unsound posture for such fractures, as the muscles which cross the knee joint posteriorly are not relaxed. Good reposition is not possible in fractures of the tibia if the tendo Achilles is not relaxed.

All these disadvantages are overcome in the skeleton type of supporting splint, named after Braun, without in any way losing the advantage of support by soft material which is a feature of skeleton splinting. It is this type of splint which is used almost exclusively by Böhler for the lower limb, and it is the most popular type of skeleton splint in use in Germany, Austria, and Switzerland. In appearance except for minor differences it is not unlike the skeleton cradle splints designed and made in Egypt during the war by Professor Hey Groves for use in our army hospitals. I had the good fortune a few years ago to observe Braun's splint in use at the Workmen's Accident Hospital, Vienna, on 14 patients, over a period of several weeks, and was struck with the obvious comfort they enjoyed. I was present at the admission of several femur cases, so that I was able to follow the treatment from its inception.

Outline drawings illustrating this splint in use for both intrinsic and extrinsic traction were given in part I of this paper, page 36, figures 13 to 15, and a detailed diagram of an adjustable model is given on page 36, figure 12. I have to thank Mr. Sharpe, D.C.M.E., for his help in this matter. For a full description of its use the reader should consult Professor Böhler's book; little difficulty will be experienced with it.

It will be easily seen that Braun's splint is stable, and allows the knee to remain in flexion, with the leg and thigh in the most suitable position for the application of extension either directly from the bone or by adhesive on the skin. No suspension cords are required to steady it, and the support which is sometimes used with a Thomas' splint is incorporated in

the splint. The large padded and, in my opinion, unnecessary ring is absent. Extension may be by intrinsic traction in the case of fractures below the knee. In extrinsic traction the weight of the body acts counter to the applied weights by elevation of the foot of the bed. The principle of the double-inclined plane, so essential in many fractures of the leg and thigh where relaxation of the tendo Achilles must be secured, is clearly applied, and permits direct extension from the knee without any additional leg flexion piece. For direct extension from the heel nothing could be simpler than the pulley arrangement which forms part of the splint.

One such splint has been allotted to each district hospital in the proposed standard scale (part I, page 35). It is cheap, and easier to make than a 'Thomas' splint as it does not require the services of a cobbler or upholsterer to make a padded ring. There is one important feature which needs stressing. In a 'Thomas' splint the slings are allowed to sag in a semi-circle to hold the limb; in using a Braun splint it is necessary to have these slings taut. The material should be applied in a continuous bandage across the side rods so as to form a firm but resilient bed for the limb.

EXTENSION AND TRACTION APPLIANCES

Manipulative reduction of fractures is another way of expressing the mysterious procedure known to the layman as 'setting' a fracture. The modern surgeon avoids manipulation as much as possible. If a piece of wood is broken across and we wish to fit the splintered ends nicely together we draw the fragments apart and then approximate them in the line of their long axes. The jagged ends will then interlock neatly. Manipulation to force the splintered ends into position without drawing them apart will only disarrange the fragmented ends and increase the damage before re-alignment is secured. This principle should be applied as often as possible in fractures. Deliberate, steady, adequate and sustained traction should be made in the direction of the upper fragment until the broken ends can be made to resume their proper positions with respect to each other. The extension is maintained until a suitable fixation appliance is attached to the limb. If the extension is removed before this is done the displacement may recur.

The tendency to use fixed frames with screw traction to reduce displacements before fixing the limb in a cast or other form of splint is increasing. Hawley's fracture table is an example of this kind of frame that can be adapted for every part of the body. Bohler has a special frame for each extremity. If all fractures occurring on a railway were concentrated at one centre, it would be possible to bring such apparatus into regular use, and to expect the development of the necessary skill among special members of our staff. The

number of fractures occurring in each district, however, is not large enough to justify the issue of an appliance, such as the Hawley table, to each district hospital, and I do not believe that the standard of fracture treatment at present warrants the heavy outlay. To my mind the demand for these specialized items should come from the districts and the will to use them will in due time provide justification for their supply. Nevertheless, I am convinced, both from personal experience and from post-graduate observation in Europe, that some form of traction appliance is essential in certain cases. I do not think it is possible to set up the lower limb properly in plaster for injuries near the hip, without its aid.

To apply this principle of continuous traction in the case of fractures of the lower limb, a perineal pillar with supporting bracket for the sacrum is necessary. The apparatus is illustrated on pages 153 and 155. The pillar must in all cases be firmly padded to the thickness of about two inches with wool and bandage to avoid injury to the urethra. In cases where the traction rods illustrated in figure 30 are not available two assistants are necessary. The pillar and bracket are clamped to the lower end of the operation table, and the patient raised about six inches by means of a box for the head and shoulders, and the bracket for the sacrum. The legs are extended by the assistants each holding an ankle. Two tables or stools of suitable height are provided for the elbows of the assistants so that they can continue traction without undue fatigue. The operator is now free to assist by pressure on the great trochanter in cases of fracture of the hip. As slow abduction with extension is made it may be possible for him to feel the fractured end of the lower fragment disengage and slip down over the upper margin of the rim of the acetabulum. The reduction can then be checked by measurements, and the plaster applied while the correct position is maintained. Where screw traction rods are available, as shown in figures 27 and 30, the extension is steadily increased by the screws and the exact value of the pull can be read off if a Salter's balance is interposed between the foot and the screw pillar.

By modifying the position of the patient with reference to the perineal pillar it is possible to use this appliance for fractures below the knee and for the upper limb. Where continuous traction by means of weights and a Thomas or Braun splint is used, such an apparatus is not essential, but it is indispensable for high fractures of the femur which are to be treated in plaster.

I am indebted to Mr. H. Mullineux, A.E.E., Jhansi, for his assistance in the design and construction of the traction appliance for the lower extremity.

It is unreasonable to suppose that no additional damage to the bone is done by forcible

the splint. The large padded and, in my opinion, unnecessary ring is absent. Extension may be by intrinsic traction in the case of fractures below the knee. In extrinsic traction the weight of the body acts counter to the applied weights by elevation of the foot of the bed. The principle of the double-inclined plane, so essential in many fractures of the leg and thigh where relaxation of the tendo Achilles must be secured, is clearly applied, and permits direct extension from the knee without any additional leg flexion piece. For direct extension from the heel nothing could be simpler than the pulley arrangement which forms part of the splint.

One such splint has been allotted to each district hospital in the proposed standard scale (part I, page 35). It is cheap, and easier to make than a Thomas' splint as it does not require the services of a cobbler or upholsterer to make a padded ring. There is one important feature which needs stressing. In a Thomas' splint the slings are allowed to sag in a semi-circle to hold the limb; in using a Braun splint it is necessary to have these slings taut. The material should be applied in a continuous bandage across the side rods so as to form a firm but resilient bed for the limb.

EXTENSION AND TRACTION APPLIANCES

Manipulative reduction of fractures is another way of expressing the mysterious procedure known to the layman as 'setting' a fracture. The modern surgeon avoids manipulation as much as possible. If a piece of wood is broken across and we wish to fit the splintered ends nicely together we draw the fragments apart and then approximate them in the line of their long axes. The jagged ends will then interlock neatly. Manipulation to force the splintered ends into position without drawing them apart will only disarrange the fragmented ends and increase the damage before re-alignment is secured. This principle should be applied as often as possible in fractures. Deliberate, steady, adequate and sustained traction should be made in the direction of the upper fragment until the broken ends can be made to resume their proper positions with respect to each other. The extension is maintained until a suitable fixation appliance is attached to the limb. If the extension is removed before this is done the displacement may recur.

The tendency to use fixed frames with screw traction to reduce displacements before fixing the limb in a cast or other form of splint is increasing. Hawley's fracture table is an example of this kind of frame that can be adapted for every part of the body. Bohler has a special frame for each extremity. If all fractures occurring on a railway were concentrated at one centre, it would be possible to bring such apparatus into regular use, and to expect the development of the necessary skill among special members of our staff. The

number of fractures occurring in each district, however, is not large enough to justify the issue of an appliance, such as the Hawley table, to each district hospital, and I do not believe that the standard of fracture treatment at present warrants the heavy outlay. To my mind the demand for these specialized items should come from the districts and the will to use them will in due time provide justification for their supply. Nevertheless, I am convinced, both from personal experience and from post-graduate observation in Europe, that some form of traction appliance is essential in certain cases. I do not think it is possible to set up the lower limb properly in plaster for injuries near the hip, without its aid.

To apply this principle of continuous traction in the case of fractures of the lower limb, a perineal pillar with supporting bracket for the sacrum is necessary. The apparatus is illustrated on pages 153 and 155. The pillar must in all cases be firmly padded to the thickness of about two inches with wool and bandage to avoid injury to the urethra. In cases where the traction rods illustrated in figure 30 are not available two assistants are necessary. The pillar and bracket are clamped to the lower end of the operation table, and the patient raised about six inches by means of a box for the head and shoulders, and the bracket for the sacrum. The legs are extended by the assistants each holding an ankle. Two tables or stools of suitable height are provided for the elbows of the assistants so that they can continue traction without undue fatigue. The operator is now free to assist by pressure on the great trochanter in cases of fracture of the hip. As slow abduction with extension is made it may be possible for him to feel the fractured end of the lower fragment disengage and slip down over the upper margin of the rim of the acetabulum. The reduction can then be checked by measurements, and the plaster applied while the correct position is maintained. Where screw traction rods are available, as shown in figures 27 and 30, the extension is steadily increased by the screws and the exact value of the pull can be read off if a Salter's balance is interposed between the foot and the screw pillar.

By modifying the position of the patient with reference to the perineal pillar it is possible to use this appliance for fractures below the knee and for the upper limb. Where continuous traction by means of weights and a Thomas or Braun splint is used, such an apparatus is not essential, but it is indispensable for high fractures of the femur which are to be treated in plaster.

I am indebted to Mr. H. Mullineux, A.E.E., Jhansi, for his assistance in the design and construction of the traction appliance for the lower extremity.

avoid pressure and irritation where movement occurs. Close inspection of the limb must be enjoined on the ward staff for the first 24 hours. Swelling, blueness and pain are danger signs. If any of these occur the splint must be split immediately. A very mild degree of swelling without pain and with good sub-onyehial circulation however need cause no alarm and will probably disappear with elevation of the limb. After some experience it is possible to apply good moulded splints without any preliminary padding. These are especially useful for lower leg walking irons on account of their smaller bulk and weight.

Before beginning the application of a bandage a basin of thin plaster cream should be made ready. Half to one pint of lukewarm water in a basin is sprinkled on its surface with plaster powder. Lumps should be broken up with the fingers before being dropped into the water. The water is stirred with one hand while the sprinkling is continued until the powder ceases to sink readily below the surface of the water. The consistency of the mixture will then be about that of rich newly-drawn milk or perhaps a trifle thicker. If allowed to be thicker than this it will set before the splint is finished and be of no use for its special purpose. This cream is used for continual smearing of the layers of the bandage as they are applied by the surgeon. As the splint is nearing completion the cream will have set to a sufficiently stiff paste to finish off the ends of the plaster neatly. If the amount of cream is insufficient or has set hard too quickly, a fresh lot must be quickly prepared. It is useless to add more water to plaster which has begun to set in the hope that it can be thinned again. The result will only be a 'lumpy' mess quite unfit for plaster work.

Plaster bandages should be immersed in lukewarm water just before use. Only one bandage should be immersed at a time, a new one being added to the water by the nurse or assistant when the one being applied is nearing its end. Immersion is complete when the bandage ceases to bubble. If immersion is continued much longer the plaster in the bandage will have set and if now used it will be found that the layers of the material will not adhere. Bandages should not be wrung or squeezed before being applied. The better saturated the bandage the more effectively will the plaster set. During the application of the bandage the bowl or basin containing the plaster cream is held under the limb so as to catch the overflow of excess water and suspended plaster. This is reapplied immediately by the assistant.

Care should be taken that the fingers or any adjacent projections on the table or extension apparatus do not cause any indentations in the plaster while it is soft. A skilled assistant holds the limb if necessary with the flat of the hand or by a rubbing motion. Pressure sores will result from indentations due to unskilful handling.

Turns and twists tend to produce a rope effect in the moist bandage and because of the danger of constriction effects should be avoided as much as possible.

When the bandaging is complete the splint will remain soft for some time, according to the state of the weather. Care should be taken that displacement does not occur during this period. Drop foot and drop wrist are very liable to appear after the plaster has hardened if this is neglected. The heel should not be rested on the bed or table until the plaster is hard. The date of application of the plaster should be clearly printed in ink or indelible pencil on the plaster when finished.

Large plasters such as those around the hip or shoulder should be strengthened across the joint lines by strips of Cramer's wire splinting incorporated in the layers of the bandage.

Bivalve or split plasters, if carefully cut, can be eyeletted and hinged with tape along the back of the limb. The edges should be bound with adhesive plaster to prevent fraying and crumbling. Hip abduction plasters may be cut across at the knee and hinged at the back by incorporating a strap hinge. This allows movement and prevents stiffness of the knee. Plasters which pass as high as the waist should be cut low in a curve below the umbilicus to allow free abdominal respiration and to permit of alterations in the girth consequent on changes in the bowel and bladder content. The lateral part of the body plaster on the same side as the injury in these abduction plasters may also be cut low; this permits free expansion of the chest in old people, but does not in any way interfere with the extent of abduction which is controlled by the wall of plaster on the uninjured side.

In all cases it is wise to bear in mind that the trouble of renewing a plaster is to be preferred to the risk of a pressure sore or an ischæmic myotrophy.

Plaster is pervious to x-rays, and radiograms should be taken after application, to ascertain the condition of the bones. If reduction is not good reapply the plaster, if necessary, with the aid of a traction appliance.

In the preparation of bivalve plaster splints, a longitudinal strip of soft metal may be bandaged into the deeper layers of the plaster; this is cut down upon and facilitates the splitting process.

The finishing off at the ends of a plaster is done with an old scalpel with a strong blade. Cream is used to smooth the rough edges. Windows for the dressing of wounds, or to provide 'scratch' apertures, are made in the same way before the plaster has hardened.

It is not necessary that all plasters be made by bandaging the affected part. Moulded splints are useful in certain situations such as the dorsum of the forearm and the back of the leg and thigh. The soaked bandage is passed back and forth on a smooth surface to the required length so as to make a plaster pad

three-sixteenths to a quarter of an inch in thickness. The width depends on the width of the part affected. This pad is placed on the affected part while still soft and moulded by pressure. It can be fixed to the part by means of a non-plaster bandage. It will set with a perfect fit to the part. Similar pads may be used for strengthening large plasters. In the manufacture of large shells for the recumbent treatment of spinal injuries considerable sections of the shell may be made in this way with much saving in time.

The removal of a plaster is often a laborious process. Chemical softening agents do not result in much saving of time. Special shears and saw are provided in the standard scale. These instruments should be treated with care in the same way as other surgical instruments and not allowed to lie about as general tools for the use of anyone in the hospital. Plasters which are not required as bivalves or moulded splints after being cut may often be very easily removed by unwinding the bandage if the end is carefully looked for. This method is simpler than cutting.

ANALGESIA IN FRACTURE TREATMENT

Novocaine solution, two per cent, should be used. The technique aims at placing the solution in the hæmatoma around the fractured ends. Fifteen to twenty cubic centimetres are necessary. A total of 50 to 60 c.cm. may be used in multiple injuries in a single case. All instruments must be sterile. The skin is painted with tincture of iodine. The needle should not be touched with the hands, nor should any handling of the plunger occur. The needle should be held by means of a dissecting forceps. The mount of all record pattern needles will be found specially suited for this.

The novocaine should be administered just before the fracture is to be fixed in splints or other means of support. If done as a preliminary to transportation without adequate fixation, or if the limb is allowed to remain unsupported with the patient not under supervision, the displacement may be aggravated and the soft parts damaged by the patient's own movements owing to the remarkable freedom from pain which results. A closed fracture may thus be opened, especially in the leg.

A 10-c.cm. record syringe is necessary. For bones lying at a depth of not more than an inch from the surface a no. 12 hypodermic needle (3 cm.) is satisfactory. For the hip a serum needle of at least 6 cm. is required, to ensure reaching the bone.

The break in the bone is accurately located by palpation, and the needle passed directly down to strike the bone. Five c.cm. is injected and the syringe detached from the needle, leaving the latter in the tissues. In doing this, steady the needle mount with the forceps and not with the fingers. If the hæmatoma has been tapped blood-stained solution will slowly

escape from the needle. The entire 15 to 20 c.cm. may then be injected with perfect confidence that analgesia will be established in the course of a minute or two. If no blood-stained fluid appears from the needle, it should be re-directed after partial withdrawal in a fresh attempt to tap the hæmatoma. Where the hæmatoma is small, as may happen in cases with little or no displacement, it may be impossible to reach it. In such cases two or more injections are made down to the bone from different points on the circumference of the limb so as to encircle the break with solution. This will produce effective analgesia, but has the disadvantage of needing several punctures.

The anaesthesia lasts 2 or 3 hours, but the injection may be repeated if necessary. In the case of open (compound) fractures the needle must be entered from a sound area of skin. There is no closed hæmatoma in such cases so that the solution must be forced into the tissues surrounding the fracture. If the infiltration has been satisfactory, the solution will be found to ooze into the wound as the injection is made. If the solution wells up into the wound the needle is not in the tissues but in direct communication with the surface, and anaesthesia will not result. In such an event the needle must be withdrawn slightly. Two or more injection sites will be necessary to encircle the fracture completely.

After the lapse of a few days from the time of fracture the hæmatoma no longer exists in a fluid state, and diffusion of the solution does not take place effectively and rapidly in the fractured area. Analgesia may nevertheless be obtained by injecting from three or four points round the site of fracture after the manner indicated in cases where the hæmatoma is not located. During the past six months I have used this form of analgesia in the following cases:—The fractures of the neck of the femur, the internal malleolus, the radius, the fibula and a metatarsus, Pott's fracture, Colles' fracture, and dislocation of the elbow.

MISCELLANEOUS ITEMS

Figures 32 to 39 illustrate a number of points in the preparation and application of apparatus for the treatment of fractures; the figures and captions are sufficiently self-explanatory to obviate the necessity for any detailed description.

Fractures of the jaw.—Attention should be directed to the teeth whenever present and the restoration of natural bite or dental occlusion held in view. The surgeon will be well advised in all jaw fractures with displacement to request the help of a dentist. A specially fashioned intraoral splint with dental treatment of dental sepsis is the safest and soundest procedure; no special splint will therefore be found in the scale for jaw cases. I believe that an external splint is of little or no use in any case which

really requires splinting to prevent displacement.

Sinclair's glue.—For the preparation of this the following ingredients are required :—

Glue, carpenter's ordinary	50 parts
Glycerine	2 "
Calcium chloride ..	2 "
Thymol	1 "
Water	50 "

Soak for 12 hours and then melt in a water bath. Store in a wide-mouthed well-corked bottle.

Melt in a basin of hot water when required for use.

Apply with a brush direct to the limb. The strokes of the brush should be against the direction of the growth of the hairs so that they lie opposite to the natural direction when the traction material is applied to the limb. The patient is more comfortable when this is done. The limb need not be shaved. After applying the first layer of traction gauze or other material a second or third layer may be applied after painting more glue on the preceding layer.

The glue will have set sufficiently in 20 minutes and weight may then be applied to the traction stirrup. This glue may also be used for sock and glove traction for the foot and hand.

A glue which does not require heating may be made as follows :—

Resin	50 parts
Alcohol	50 "
Benzine	25 "
Venice turpentine ..	5 "

It should be kept in a well-stoppered bottle to prevent evaporation. If this occurs the skin is liable to irritation with this glue owing to alterations of the proportions of the components.

ADDENDUM

In part I of this paper, which appeared in the January number, the following items were omitted from the standard scale of fracture equipment :—

Balkan beam (as shown in figure 7, page 31), one to each district hospital.

Thomas' abduction arm splint (figure 1, page 31), two to each district hospital and one to each dispensary.

Medical News

PROPOSAL FOR AN INDIAN INSTITUTE FOR MEDICAL RESEARCH

In connection with this proposed institute of medical research, an appeal, from which we have extracted the following paragraphs, has recently been issued.

'Workers in India have been feeling, for some years past, the need for a research institute where original investigations in medical sciences could be carried out and the problems bearing on the promotion of national health could be intensively studied. It is not strange that in India the rate of mortality is so colossal, the average span of life so short and the standard of health generally so much lower than in the countries of the West. A century ago the standard of health in western countries was not much better than that in India now but sanitation and education, backed by organized scientific enquiries into all the problems connected with health, have resulted in a rapid and steady improvement of the health of the people. Scientific research carried on for its own sake as also with the determination of applying it, wherever possible, to the service of the community, is, we feel, necessary for raising the standard of both the health and the efficiency of our people.

It will be generally agreed that very little work has been done on those lines in this country outside the few government institutions, the number of which is inadequate to meet the needs of our country. During the last few years assurances have been received from a number of keen and able workers who are prepared to devote their lives to make this scheme a success. The objects of this institute will be to carry on research in the medical sciences, to train a band of research workers, to apply the knowledge obtained to clinical practice and to preventive medicine, and to disseminate the knowledge of hygiene among the masses, making its services available to them either free or at a low cost.

The intention is to found an institute which will be called "The Indian Institute for Medical Research",

with six departments to start with, namely, (1) bacteriology and pathology, (2) tuberculosis, (3) biochemistry and nutrition, (4) protozoology, (5) experimental pharmacology and indigenous drugs enquiry, and (6) diagnostic laboratory and clinical work, with which the propaganda and preventive service will be incorporated. More sections will be added as soon as sufficient funds are available.

The diagnostic department will be in direct touch with the needs of the people and will try to help institutions, local bodies and medical men with the diagnosis of communicable diseases either free or at a nominal cost and will distribute biological products also at a low cost, if not altogether free. The object of developing this service is to facilitate preventive measures even in very modest homes among all strata of society. It will also be the function of this department to arrange for educative propaganda for the prevention of diseases.

It is desired that the institute shall provide a centre for an increasing band of research workers, who may come in as post-graduate students for whom regular training arrangements are contemplated. The institute may be affiliated to a university and may receive State aid. The institute will also act as a consultative body for the determination of the purity and potency of sera, vaccines and drugs. Indian markets are now flooded with all kinds of adulterated and under-strength products and there is absolutely no way to control or check the purity of medicines and drugs.

The results of its researches will be published periodically in the form of *Transactions* of the institute.

In countries like Europe and America, large donations and endowments are made for this scientific research work, which ultimately does the greatest good to the people. In our country, donations are frequently given for religious endowments. The problem of the health of the people of this country has not attracted the attention of those who could afford to spend money

for charitable purposes. We believe, however, that many in this country are now realizing the necessity for scientific investigation of vital problems of national health. If we succeed in raising the money, this institute for medical research will be the first of its kind in India organized and financed by Indians.

It has been calculated that the initial expenses for starting such an institute will be at least Rs. 1,25,000 for fittings, equipment and first year's current expenses only and a recurring expenditure of at least Rs. 1,10,000 yearly will be required for the six proposed sections. It is hoped, however, that the institute will be self-supporting after the first year. We, therefore, appeal to the generosity of the public only for the initial expenditure necessary to establish the institute and to enable it to function for the first year, namely the sum of Rs. 1,25,000. It is a small premium to pay for the benefits that will accrue, for we would emphasize that improved health means increased longevity and capacity for work, and necessary additions to the national wealth and happiness of the India to come. Notwithstanding these days of depression, we trust that public response will be prompt and generous.

The medical problems that urgently require investigation in this country are so numerous that it would be almost impossible to have too many workers devoting their time to medical research. Hitherto, as the organizers of this appeal say, Indian philanthropists have been more ready to give their money towards hospitals and dispensaries for providing medical relief, the result of whose work, though only affecting a small section of the population, is immediately obvious, than to the organization of medical research which may, and usually does, produce results which, though not so obvious, are more far reaching, more permanent and affect a greater number of persons. Hitherto research organizations, such as the Calcutta School of Tropical Medicine, the Indian Research Fund Association, and the All-India Institute of Hygiene, if not supported by Government, have had to look to Europeans and Americans for their main support; there are of course exceptions as some of the research chairs at the School of Tropical Medicine are endowed entirely by Indians.

However, it has been amply proved by the work of the above-mentioned organizations that a many-fold return may be expected from research work, and with these examples to quote it should not now be difficult to persuade philanthropic Indians that they are likely to see a good return for money which they subscribe.

Care will have to be taken that there is no duplication of work, as the subjects to be taken up by the six proposed sections are already covered by sections operating at the School of Tropical Medicine or shortly to be opened at the All-India Institute of Hygiene, but there should be no real difficulty if the spirit of co-operation which exists between these two institutions spreads to the new institute.

There are, as the instigators of this scheme say, a host of young Indian workers anxious to take up medical research when the opportunity arises. A few years ago the cry was for trained workers, now if a post is advertised there are literally hundreds of applicants of which many have excellent qualifications—not simply letters after their names, but practical experience and good work to their credit; from these it should be possible to select a team of good workers.

Whilst admitting that spacious laboratories and expensive-looking equipment do not ensure the production of useful work, shortage of apparatus and other facilities always lead to a waste of time and will very often seriously detract from the value of the work done. The Rockefeller Foundation spent about Rs. 17,00,000 on building and equipping the Institute of Hygiene and, though it may not be necessary to maintain this high standard, we feel some doubt about the sufficiency of the sum with which it is proposed to establish the new institute, and we cannot help thinking that it would be better to commence with fewer sections and open out as more money becomes available.

We note that there is a suggestion that after the first year the institute will be self-supporting. It does not seem to be made quite clear from where the money is to come, but it is presumably from patients, as fees for laboratory examinations, and from the sale of vaccine, sera, etc. But here care will have to be exercised as vested interests are at stake; private practitioners will consider that patients who can afford to pay should not be withdrawn from them, and established clinical laboratories and manufacturers of biological products may not welcome a new rival. Finally, there is a suggestion that State aid might be sought: but at the present time money is not pouring into the State coffers and the grants to existing institutes have been cut, so that it is unlikely that this hope will materialize—at any rate for some years.

These, however, are difficulties such as always have to be overcome at the inception of any new scheme and we have little doubt that the organizers of this one will see their way, once their scheme develops. The ideal is a very worthy one, and we wish success to its accomplishment.—*Editor, I. M. G.*

NORMAN GAMBLE FUND AND RESEARCH PRIZE

THE Council of the Royal Society of Medicine has accepted, as a trust, the sum of one thousand pounds (£1,000) presented by Mr. Norman Gamble for the purpose of founding 'The Norman Gamble Fund and Research Prize'.

The Norman Gamble Research Prize, value £50, shall be awarded for the best original work in otology completed during the four years previous to the month of October in the year of the award. The competition for this prize shall be open to any British subject, whether lay or medical, who cares to compete, whether or not such persons be holders of or candidates for grants in aid of research.

Grants in aid of research work in otology may be made to any British subject, lay or medical, who may be recommended by the Committee of Award to receive such grants, whether or not such person be a holder of or a candidate for the Norman Gamble Prize. Moreover, such grants may be given either to persons who apply for a grant in order to carry out a specific piece of work, or to selected workers chosen by the Committee of Award to carry out certain specified work of its selection.

Any person to whom a grant in aid of research is made from this Fund shall, within such time as may be allowed by the Committee of Award, render a typewritten or printed report in the English language on the work which has been carried out under the grant, and the Committee of Award shall have the right to publish such reports.

The Committee shall not make any recommendation either for the award of the Norman Gamble Prize or for any grant in research if the papers or work under consideration are not of a sufficiently high standard.

The Committee of Award will consider applications for the prize and for grants in aid of research work in October 1934.

Applications for the prize and for grants in aid must be received by the Secretary of the Royal Society of Medicine, 1, Wimpole Street, London, W.1, not later than 30th September, 1934, and must be in accordance with the regulations stated above.

ALVARENGA PRIZE OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA

THE College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Senor Alvarenga, and amounting to about three hundred dollars, will be made on 14th July, 1934, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered.

An essay intended for competition may be upon any subject in medicine, but must be accompanied by a written assurance from the author that it has not appeared previously in print, either in whole or in part, in any form, and has not been presented elsewhere in competition for a prize. The essay should represent an addition to the knowledge and understanding of the subject based either upon original or literary research. It must be typewritten, and in English, acceptable for publication without necessity for editing by the Committee. Any illustrations should be appropriate and correctly annotated with the text. Essays must be received by the Secretary of the College on or before 1st May, 1934.

Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author.

It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; and that it may be published by the author with the consent of the College; other essays will be returned upon application within three months after the award.

The Alvarenga Prize for 1933 has been awarded to Drs. Harry Shay and J. Gershon Cohen of Philadelphia for their essay entitled: 'Experimental Studies in Gastric Physiology in Man'.

MEDICAL ASSOCIATION, COIMBATORE

THE annual dinner of the Coimbatore Medical Association was held in the premises of the new block of the Moses Gnanabharanam Eye Hospital at 8 p.m. on Thursday the 4th December, 1933. After the dinner Dr. Sangameswara Iyer was proposed to the Chair and the report for the concluding year was read by the Secretary, Dr. S. Gurubatham, and adopted. New officers for the coming year were elected—

President: .. Dr. C. N. Anantaranga Rao.
 Vice-President: .. Dr. N. Pratap.
 Secretary: .. Dr. Gurubatham (re-elected).
 Assistant Secretary: Dr. N. Velappan.
 Management: Committee Members:—
 Dr. L. Seshadrinathan.
 Dr. R. Sundararajan.
 Dr. Sangameswaran.
 Dr. K. Narayanan.

The newly-elected President Dr. Anantaranga Rao thanked the members for the honour done to him, discoursed on his long experience in the medical profession, and gave a few words of advice to the young members.

Dr. Sundararajan then put forward a few suggestions, for the better working of the association in the coming years.

Current Topics

The Therapeutics of Malaria: Third General Report of the Malaria Commission

(Abstracted from the *Quarterly Bulletin of the Health Organization of the League of Nations*, June 1933, Vol. II, No. 2)

THE present report appears at a time when knowledge on malaria, after many years of little or no progress, seems again to be advancing. The advance is due chiefly to notable additions to knowledge on the biological aspects of the subject, but the discovery and manufacture of effective synthetic antimalarial remedies gives promise of improving the treatment of the disease and of extending the purposes for which specific drugs can be used. This being so, the Commission has considered it desirable to include under the title 'therapeutics of malaria' the whole range of general and particular aims which practising physicians and public health workers now hope to accomplish by the use of specific antimalarial drugs. But they wish it to be understood quite clearly that, in their opinion, the new synthetic remedies now available are still in the experimental stage, and they consider that the time has not yet come when any of these drugs can be recommended as substitutes for, or in preference to, quinine and other preparations of cinchona bark. The situation to-day may be considered to be analogous in some respects to that which arose after the epoch-making discovery of the mosquito cycle of malaria nearly forty years ago. Now, as then, new knowledge of fundamental importance is available, but we have to learn how it can be applied and utilized effectively in practical antimalarial work. Trustworthy information on the practical application of the new knowledge cannot be obtained quickly, and it is probable that many more discoveries, both biological and chemical, will have to be made before it will be safe to say that the solution of the malaria problem in the world generally is appreciably nearer than of old. What can be said on reviewing the information given in the present report is that additions to knowledge on the

biological side permit the treatment of malaria to be considered in a more rational manner and with greater attention to the past and future history of the case than heretofore, and that the possession of new antimalarial drugs with specific properties different from those of quinine opens the way to some preventive aims which previously could not be realized. These aims—particularly true causal prophylaxis, the prevention of relapses and gametocyte therapy—have been given a prominent place in this report, not because any very striking advance towards their realization can be recorded, but in order that workers may be in a better position to appraise the value of the numerous reports on new remedies which issue like a flood from the medical and lay press. On plasmoquine alone more than 600 articles have already been published and the literature on atebirin seems likely soon to become equally voluminous. It is in these circumstances that this review of the present position of knowledge on the new drugs as well as on quinine and other cinchona alkaloids have been made in the hope that it may be of service to all who are concerned with the therapy and prophylaxis of malaria.

In the first place, the Commission would like to emphasize that, from the medical point of view, the question of competition between natural and synthetic antimalarial remedies does not arise. The treatment of malaria by the physician would not be advanced by producing quinine synthetically or by producing synthetic remedies with an action and toxicity so similar to the action and toxicity of quinine that they could be used only as 'substitutes' for that drug. From the medical point of view, what is required of a new product is that it should be effective for some therapeutic or prophylactic purpose for which quinine is known to fail, and—if it is so—that its use for the particular purpose should involve the patient in no risk of toxic symptoms. The latter is as important as the former.

Having regard to these criteria, the following brief recapitulation of the uses to which available specific remedies are applicable may now be given:

Sporozoite therapy (true causal prophylaxis).—No drug is known which, taken in harmless doses, can be guaranteed to act as a true causal prophylactic.

Clinical prophylaxis.—The Commission is of opinion that quinine is effective for this purpose and that it is the best drug to use. The correct plan is to take a daily dose of 0.4 grm. (6 grains). The daily dose should be taken throughout the period of residence in a malarious area and, to avoid a relapse, for several months after leaving it. Atebrin taken in a daily dose of one tablet (0.1 grm.) is also effective as a clinical prophylactic, but it cannot ordinarily be used for the purpose, as even this small daily dose quickly colours the skin yellow.

Treatment of the attack.—The Commission is of opinion that it is not good practice to treat attacks of malaria in the acute stage with more than one of the specific drugs available. They desire also to state without any qualification that, in their view, plasmoquine should not be used in the treatment of acute attacks of any form of malaria. Thus the choice of specific drugs lies at present between quinine and atebrin. Neither fulfils the requirements of a *therapia sterilisans magna* and the Commission does not consider that, for general use, one of them should be preferred to the other. The great advantage of possessing two curative drugs is that, in cases which seem resistant to treatment with one of them, trial of the other can be made. For the treatment of acute attacks of benign tertian and quartan malaria, quinine and atebrin seem to be about equally effective; but atebrin is definitely superior to quinine for the treatment of acute attacks of malignant tertian (subtertian) malaria. This statement does not imply that good results cannot be obtained with quinine or that it is good practice always to use atebrin instead of quinine for the treatment of acute attacks occurring in patients infected with *P. falciparum*. In connection with this and several other therapeutic questions, the Commission has drawn particular attention to the discovery that the therapeutics of malaria, like every other aspect of the disease, is much more a local and individual problem than has hitherto been thought, and has suggested that workers in different countries throughout the world should endeavour, as soon as possible, to ascertain by carefully controlled experiments what is the comparative susceptibility to quinine and to atebrin of the particular strains of parasite locally prevalent.

The Commission considers that curative doses of quinine or of atebrin for treatment of an attack should not be continued longer than seven days, and that treatment for five days will often suffice.

Treatment to prevent relapses.—No drug or combination of drugs seems yet to be available which will sterilize all the parasites in the human host and thus prevent the possibility of relapse. Neither treatment with quinine alone nor with atebrin alone, nor treatment with either of these in combination with plasmoquine, however intensive or prolonged the treatment may be, can be guaranteed to do so. For this and other reasons which are stated in the report, the Commission does not consider that it is in the best interest of patients to endeavour to combine a plan of treatment designed for the prevention of relapses with a plan having for its object the clinical cure of an acute attack. They believe that treatment designed to prevent relapses should not be begun until at least a week has elapsed since recovery from the acute (primary) attack.

Secondly, the Commission has discussed in the report the problem whether a lower percentage of relapses can be brought about by plasmoquine *plus* quinine than by quinine alone. It was pointed out that, as this mixture does not produce a new compound in the stomach, each drug exerts only its own specific action, and that the doses of plasmoquine which are given with quinine in this method of prophylaxis are smaller than those which exert a specific effect on sporozoites and

trophozoites during the incubation period of the disease or on merozoites and schizonts during the developed attack. This being the case, and it being also known that quinine does not prevent relapses, the proposition that relapses can be reduced by giving ineffective doses of both drugs together is paradoxical. Attention was also drawn to some reports in which the claim is made that a lower percentage of relapses can be brought about by mixing non-specific drugs (e.g., bicarbonate of soda) with quinine than by using quinine alone, and to others in which the reported relapse rate following treatment with plasmoquine *plus* quinine was 100 per cent. It was mentioned also in connection with this subject that the percentage of relapses following any system of specific treatment (and even the percentage following no specific treatment) varies greatly in different countries, in different localities of the same country, and in different individuals. Some of the factors to which these differences may be due were briefly described. It appeared from this account that the problem is one which cannot easily be solved by clinical trials conducted under field conditions in which few of the many factors concerned are known.

For these reasons and having regard also to the cost of particular systems of treatment, the Commission does not at present recommend that a system of treatment with quinine *plus* plasmoquine ('quino-plasmoquine', 'plasmoquine compound', etc.) should be adopted for reducing the incidence of relapses. Having regard, however, to opinions on the subject of 'chemo-therapeutic activation', the Commission would be prepared to review this recommendation if it could be shown by controlled laboratory trials on bird malaria or on monkey malaria, and confirmed by clinical trials under known conditions on induced malaria in man, that it is, in fact, the case that the addition of a non-effective dose of plasmoquine to quinine enhances the action of this specific remedy.

The plan which the Commission favours for preventing relapses of malignant tertian malaria is different from the plan suggested for benign tertian and quartan malaria. This is because they believe that, in cases of malignant tertian malaria, there is a much better prospect of destroying all the parasites present in the system than in infections with the other species. They suggest that, in malignant tertian malaria (*P. falciparum*), when treatment of the primary attack has failed to bring about a permanent cure, the curative course should be repeated in the first recrudescence. Their recommendations regarding the present relapses can be summarized thus:—(1) There is not at our disposal any drug, or any combination of drugs, which can be guaranteed to sterilize all the parasites in the human host and so to prevent the possibility of relapse.

(2) For this reason no good purpose is served by endeavouring to bring about sterilization of all the parasites during the primary attack.

(3) In nature, relapses cease to occur when the defensive mechanism of the human host has acquired sufficient power to overcome the fever and other clinical symptoms which the parasites cause in non-immune persons. The frequency and severity of relapses are dependent chiefly on the amount of defensive power which the infected person possesses naturally or acquires as a result of previous attacks. A scientific method of preventing relapses should be based on this knowledge or should take this knowledge into account by allowing an infected person to acquire as much defensive power as possible. Persons who are treated with large doses of quinine or other specific drug at the first onset of fever in their primary attack and in each relapse get no opportunity of acquiring sufficient defensive power to prevent relapses. Persons who are so treated usually relapse every month for a very long period. During the primary attack, it may not be safe to abstain for a day or two from giving a specific drug, but it is quite safe to do so in the first and any subsequent relapse.

(4) Thus, in a scientific system for the prevention of relapses, no attempt is made to give 'treatment for

the prevention of relapses' during the primary attack. One waits until the first recrudescence and then uses the specific remedies in such a way that they will assist, rather than hinder, the development of the patient's natural defensive forces. By repeating this plan with the same watchfulness during the second recrudescence (using the specific drug at a later period and more sparingly than in the first recrudescence) and again, if necessary, during a third recrudescence it happens, in most cases, that the patient becomes fortified or preimmunized against the disease to the extent that he not only ceases to suffer from relapses but fails to have an attack when he is reinfected.

(5) In the Commission's view, an endeavour to follow that plan should be made for the prevention of relapses of benign tertian and quartan fever. But they consider that, for preventing relapses of malignant tertian fever, it is justifiable to endeavour to sterilize all the parasites by specific drug therapy during the first recrudescence. For this disease the primary attack should be cured by a five or seven days' course of treatment with quinine or with atebria and, if the patient has a recrudescence, this should be treated with a therapeutic course of five or seven days, but using the specific drug which was not used in the primary attack. If treatment during the first recrudescence is not successful in preventing relapses, therapeutic treatment of the third recrudescence should be delayed as long as possible in order to permit the patient to acquire some defensive power.

(6) The Commission believes that, when it is not considered justifiable or practicable to prescribe a system for the prevention of relapses which is based on the above principles, the best practice is to adopt a system of 'clinical prophylaxis' consisting of the administration of a small dose of quinine (0.4 grm.) daily throughout the period of residence in the malarious country and for several months after leaving it. This course should be begun about a week after cure of the primary attack. It is claimed for this system (a) that it protects individuals against serious attacks; (b) that, because it does not entirely eradicate the infection, the defensive mechanism of the body is continuously at work and becomes increasingly powerful as time goes on ('acclimatization without risk'); (c) that it reduces the number of gametocyte carriers and their capacity for infecting mosquitoes; (d) that it enables troops and agricultural and other workers to carry on their daily tasks.

*Prevention of spread (gametocyte therapy).—*As quinine and atebria are each effective for destroying gametocytes in benign tertian and quartan malaria, difficulty arises only with regard to the gametocytes of malignant tertian malaria (crescents) against which those drugs have only a feeble action. Plasmoquine, however, has a powerful action against them. The doses for preventing crescent carriers from infecting mosquitoes should be given twice a week during the period when crescents are present in the peripheral blood. The Commission is of opinion that laboratory and field trials should now be conducted with doses up to 0.02–0.04 grm. in order to ascertain the minimum effective non-toxic dose.

Lastly, the Commission desires to make the following general remarks, which include some suggestions for future study.

It is inevitable that a report which pretends to review modern therapeutics of malaria must deal with the subject from the point of view of persons who are in a position to obtain expert medical advice and effective care rather than from that of the mass of the population of malarious countries. The report does not contain information on plans for treating out-patients who attend at hospitals and dispensaries or the numerous cases of acute and chronic malaria which are discovered during the course of malaria survey work in the field. It is obvious that, so far as methods of treatment and prophylaxis can be put into practice, the same principles are applicable to all classes of

people, but it would require a separate report to describe, even briefly, the arrangements which would be necessary or desirable for dealing with malaria by the use of drugs among large masses of people who are unable to help themselves in the matter. This is a subject to which the Commission has referred in several previous reports, particularly in its second general report, the 'Principles and Methods of Antimalarial Measures in Europe', Doc. CH/Malaria 73. In some respects, the new knowledge described in the present report makes it easier than formerly to plan an effective campaign for dealing with malaria on a large scale by the use of drugs. For example, it is no longer considered correct to use quinine or other specific remedy in large doses for prolonged periods, nor is it any longer considered correct to hold the view that relapses happen because patients are not treated early in the primary attack or are not given sufficient quinine in that attack. Again, it is no longer considered essential that everyone in whose blood one or two parasites are found during a malaria survey, or everyone whose spleen is larger than normal, should be treated as if he were an acute case of malaria or as if he were certainly a source from which mosquitoes are becoming infected. Estimates of the amount of quinine which ought to be used in a country are sometimes based on malaria survey figures of that kind, but it is not a method of calculation that can be justified. Moreover, it might be most unwise in some malarious countries (Africa, for example) to interfere too radically with the natural process by which the indigenous inhabitants acquire immunity to the disease. In a recent enquiry into malaria in Southern Nigeria it was found that, in Lagos, the malaria parasite status of persons in *ordinary health* was that 90 per cent of young children and 50 per cent of adults harbour malignant tertian malaria parasites in their blood. Similar findings in rural districts indicated that, in all probability, practically the entire African population in the Lagos area above one year of age (about 120,000 persons) harbour malarial parasites in their blood continuously. It happens frequently that medical officers in charge of maternity and child welfare centres, or engaged in school medical inspection in African towns, seek advice on the significance which should be attached to findings of that kind from the clinical point of view and enquire what preventive and curative action, if any, should be taken. They report at the same time that the children, although all of them have enlarged spleens, appear, from the results of the usual clinical inspection, to be in a normal state of health and that they attend school and occupy their playtime in the same way as healthy children would do. Evidently what is needed in those areas is, not that every one in whose blood a few parasites are found should be treated with quinine as if he were a clinical case of malaria, but that more intensive clinical investigation should be made to ascertain precisely to what degree chronic parasitism following clinical recovery from the effects of repeated infection and reinfection is, in fact, harmful to the health of the children and adults concerned, and to discover precisely at what period of life curative or preventive action may be urgently necessary or would be most helpful. It is equally evident that, in such cases, quinine, except in very small doses as a tonic rather than as a parasiticide, is less important than is a system of proper diet and other measures for improving general health.

The same selective investigation is essential before beginning a system of treatment designed to prevent carriers of gametocytes from infecting mosquitoes.

These are some of the reasons which lead the Commission to recommend that epidemiological investigations by the antimalarial survey services should be gradually supplemented by intensive clinical and parasitological studies conducted continuously for a long period on selected individuals at particular age-periods. When this can be done in an area it may become possible to replace present schemes of 'mass

treatment' by a rational scheme designed to stop malaria from being fatal and to mitigate its severity without at the same time interfering unduly with the process of acquiring immunity which is so advantageous to the populations concerned when their childhood is passed. It was on these considerations that, in 1927, the Malaria Commission was led to advise malarious countries to be content with the limited aim of organizing their medical and public health services on the principle that the correct antimalarial practice is an endeavour to reduce the severity and fatality of the disease rather than to undertake the more radical measures which are necessary when the object aimed at is complete elimination of the parasites in the area concerned.

THE FOLLOWING NOTE ON THE SUBJECT HAS BEEN COMMUNICATED TO THE REPORTING COMMITTEE BY PROFESSOR B. NOCHT, OF HAMBURG, AND APPEARS TO BE IMPORTANT ENOUGH TO WARRANT REPORTING *in extenso*.

'Up to a few years ago, quinine was the only specific remedy against malaria. However, the nature of its action is not yet fully known. Certain scientists, such as Professor Giemsa, consider that quinine is a parasitocidal remedy which has a direct action on the plasmodia of malaria. I myself and other scientists such as Muhlens do not consider that this theory has been proved; we are inclined to believe that the effect of quinine on malaria is indirect—at any rate to a large extent—in that it mobilizes and strengthens the means of defence of the organism.

The reasons in support of this view are:—

(1) That the action of quinine on malaria parasites *in vitro* is much slighter and slower than its action in the living organism.

It is, in fact, possible to transmit living malaria parasites capable of producing infection several hours after the blood has been taken from a malaria patient and quinine has been added to it up to a concentration of 1 : 5,000. I must admit, however, that there is another explanation of this inadequate action of the quinine—as the malaria parasites are outside the organism in defibrinated blood they have only a *vita minima*. However, according to chemo-therapeutic experience in general, the action of chemo-therapeutic parasitocidal remedies on pathogenic protozoa is more rapid and more marked when the latter are in a state of great activity—for instance, when they are rapidly multiplying. This also applies to quinine and malaria parasites. The young merozoites offer the least resistance to quinine when they are in the organism.

(2) That the action of quinine is more effective in the case of patients who have had several attacks of fever than among those to whom quinine was given during the first attack. Nevertheless, it would be dangerous—at all events in the case of malignant tertian fever—to lay down a hard and fast rule on this matter. In fact, undue delay in administering quinine might give time for the occurrence of increasingly severe attacks of fever and might even endanger the patient's life.

(3) That large, heavy doses of quinine are no more effective than moderate or small doses repeated several times.

Morgenroth's so-called "repulsion theory" explains the action of quinine on malaria by the fact that an appreciable part of this alkaloid, when introduced into the organism, is absorbed by the red blood corpuscles. Hence the red corpuscles can no longer serve as food for the malaria parasites, which then die. If quinine is added to defibrinated blood, a surprisingly large quantity is absorbed by the red corpuscles from the serum—a fact which I had observed and published ten years before Morgenroth. However, I do not endorse the "repulsion theory", as the statement that the red corpuscles absorb a surprisingly large quantity of quinine holds good solely in the case of blood defibrinated *in vitro*. It is a well-known fact that a few minutes after quinine has been introduced into the

living organism (even intravenously) only slight traces can be detected either in the red corpuscles of the circulating blood or in the blood plasma.

However, if we have as yet no very clear idea of the nature of the action of quinine on malaria, the clinical experience of several decades has furnished us with a series of reliable guiding principles which should be taken into consideration in administering quinine.

(1) Treatment with quinine can never be regarded as a *therapia sterilisans magna*. Relapses may occur with any kind of quinine treatment, and there is no means of preventing them. It is therefore impossible to state definitely in the case of quinine treatment that the patient is "cured"—i.e., that the infection has completely disappeared. It is not quinine but time and the organism itself which "cure" malaria patients.

(2) Quinine has no action, or in any case only an incomplete action, on the gametocytes.

(3) Large, heavy doses of quinine are no more effective than moderate doses, but may have very disagreeable secondary effects.

(4) Quinine is not a medicament which has no effect on the organism. After the prolonged daily use in large doses (for some weeks or more), apart from the well-known secondary effects, it produces—at any rate in a large number of patients—chronic poisoning, the chief symptoms of which are a lowering of the defensive and immunizing capacity to such a degree that fever and parasites recur despite the administration of large daily doses of quinine. In certain cases of chronic poisoning, fever is observed without parasites. These cases possibly include a certain number of those described by English authors as pseudo-relapses. As, after several weeks, most patients reduce of their own accord the large initial daily doses of quinine, or suspend the treatment altogether, notwithstanding the doctor's instructions, these cases of "paradoxical" fever due to quinine or of "pseudo-relapses" are not very numerous. However, they are more often found among patients under effective medical supervision—as, for instance, during the war in the military hospitals, I myself came across a whole series of these strange cases among our troops in Macedonia.

(5) In certain circumstances, quinine may cause more or less copious (extensive) skin hæmorrhages either in cases of idiosyncrasy or as a result of the improper, chronic use of large doses, or of the prolonged administration of small doses—such as are employed, for instance, for quinine prophylaxis. Similar observations have already been made in our naval ships in which prolonged quinine prophylaxis was strictly applied.

(6) In susceptible patients, quinine may cause hæmolytic or serious hæmoglobinuria; this occurs in certain cases after a single dose. In the course of my investigations I have found that quinine stimulates to such a degree a whole series of hæmolytic antibodies in the living organism of the animal and increases their activity so greatly that even such small doses of hæmolytic agents as would not by themselves cause intravascular hæmolytic or hæmoglobinuria produce these effects when combined with quinine. Such substances are, for instance, hæmolytic serum, cobra venom, lysocytine and bile salts. It is probable that, in certain cases of malaria—particularly patients suffering from a chronic infection—hæmolytic substances may be formed (autolysin?) and be activated by quinine. I cannot admit, however, that it has so far been possible to prove the presence of such hæmolysin.

While I am of opinion that the six guiding principles mentioned above should be taken into consideration by every doctor treating malaria with quinine, I do not propose to lay down hard and fast rules for this treatment, which must be applied in different ways according to the character and severity of the infection, the nature of the patient and also, in many cases, the district.

The campaign against malaria as a social disease by means of treatment with quinine, which should be as

complete, as thorough and as appropriate as possible, requires—as does, of course, the treatment of this disease by other remedies—a suitable, extensive and effective organization, and, in particular, adequate medical and auxiliary personnel, a sufficient supply of quinine, the goodwill and comprehension of an intelligent and disciplined population. Without this collaboration on the part of the population, it would merely be a waste of money to distribute quinine on a large scale. In most tropical districts, the intelligent collaboration of the population (natives) will be lacking and, moreover, the indolence of the natives and their antipathy to quinine are usually so great as to make it impossible to give adequate out-patient treatment on a large scale. Even where the population is intelligent, disciplined and anxious to help, the result of the campaign against malaria by means of the treatment of patients with quinine likewise depends on a large number of other factors (nature of the malaria, climate, state of nutrition, general well-being, housing). When it is possible to apply the measures under favourable conditions, malaria mortality is nearly always reduced to a minimum, there is a general decline—sometimes very slow—of morbidity, an attenuation of the severity of the disease, and—for instance, in non-tropical countries—an appreciable reduction of malignant tertian.

Since our last conference on malaria, I have become convinced that an intensive campaign against anopheles, where this can be undertaken, does not render the treatment of patients with quinine superfluous; but, when these two measures are applied simultaneously, quicker and more successful results are obtained than with quinine treatment alone.

Of the secondary alkaloids of cinchona, quinidine is as effective as quinine; hydroquinine, which is derived from quinine, is even more effective. Cinchonine and cinchona febrifuge have to be administered in larger quantities and are less effective than quinine in malignant tertian fever. Large-scale experiments with totaquina in human malaria have yet to be carried out.

Prevention by treatment.—By this I mean the regular administration of quinine and other antimalaria medicaments to healthy individuals who have had no obvious symptoms of malaria and wish to ward off this disease. It is common knowledge that infection cannot be prevented by means of quinine. The disease may, however, remain latent. The interruption of quinine prophylaxis, climate—in particular, variations of temperature—defective nutrition, over-fatigue, etc., may cause this latent state to develop into acute infection. This kind of quinine prophylaxis, strictly applied, has given good results and can be recommended (for instance, for workmen, agricultural labourers, soldiers, etc., who at certain periods are obliged to carry out work in malarial districts—e.g., the construction of railways, harvesting or military operations). Individuals who are under treatment can go on working and follow their occupation during the critical period, provided this does not last too long; whereas, without quinine, prophylaxis morbidity might have reached 100 per cent.

The Modern Treatment of the Anæmias

By JOHN F. WILKINSON, M.D., M.R.C.P., Ph.D., M.S.C.
(From the *Practitioner*, October 1933, Vol. CXXXI, p. 409)

It is absolutely essential that before any treatment is considered for an anæmic patient a correct diagnosis should be made as to the type and cause of the anæmia; the former usually offers little difficulty but the latter may be less obvious. The importance of this lies in the fact that once treatment has been instituted further attempts at diagnosis may be completely obscured. For correct diagnosis it is necessary to make a complete clinical examination of the patient, followed

at least by a full blood count and a fractional gastric analysis. The former, of course, is essential since anæmia is commonly associated with so many diseases, especially neoplasms, gynecological or other pathological conditions, and pregnancy. In these cases attention will obviously be turned to the primary cause, and secondly to the correction of the anæmic state. In many patients, however, a primary cause may not be found and the anæmia becomes the first consideration. Fortunately more than 90 per cent of the cases of anæmia met with in general practice fall into two large groups, for which satisfactory treatment is now available and can be readily carried out at home. In the more rare blood conditions the special advantages of institutional treatment should be considered.

It will be convenient in discussing treatment to use a classification, though not perfect, based upon current etiological views and methods of treatment. In this way treatment of the vast bulk of the anæmic states becomes a relatively simple procedure. Anæmia (as applied here to a deficiency of red blood-cells and/or hemoglobin) may be due to: (a) acute or chronic blood loss as may occur post-operatively or associated with menorrhagia, etc.; (b) excessive blood destruction, as in the acute and chronic hæmolytic anæmias and familial acholuric jaundice; (c) destruction or complete inhibition of the blood-forming organs (and mechanism) as in aplastic anæmia; (d) defective functional activity of the blood-forming (hæmopoietic) system. The anæmias in the last group appear to be of the nature of deficiency anæmias since they are associated with a deficiency in either (i) the supply, formation or absorption of the anti-anæmic principle (as found, for example, in liver) or (ii) the supply, absorption or utilization of iron.

Treatment of group (a) consists in relieving the primary cause and administering therapy as in group (d) (ii) below; group (b) includes the rarer anæmias that are usually difficult to treat satisfactorily in the patient's home; special treatment is necessary according to the particular condition, the diagnosis of which may offer some difficulties; in group (c) patients with the rarer and fatal aplastic anæmias are enabled to live a little longer by repeated blood transfusions which, however, do not act in any way as a cure. Group (d) comprises the great majority of anæmic patients encountered in practice. The type of deficiency determines not only the character of the anæmia, but also the required treatment. (i) Anæmia of the type of pernicious anæmia (macrocytic hyperchromic anæmia) occurs when there is a deficiency in the supply of the anti-pernicious anæmia principle (as present in liver) to the blood-forming tissues. An adequate supply of this substance in the body is dependent upon the presence of hæmopoietin (an enzyme in the normal gastric secretion), the correct qualitative food intake, and a satisfactory alimentary absorption of the digestion products of these two; consequently, an anæmia resembling pernicious anæmia may be found occasionally in association with pyloric or chronic intestinal obstruction or stenosis, starvation, hæmolytic or 'pernicious' anæmia of pregnancy, sprue and occasionally together with or following gastro-intestinal cancer, operation (gastrectomy or gastro-enterostomy) or intestinal parasites. The anæmia in these cases usually shows a satisfactory response to adequate replacement therapy.

The important feature to bear in mind is that these anæmias appear to be true deficiency anæmias and require an adequate supply of the specific anti-anæmic principle of liver or stomach in order to maintain health. On the other hand, the anæmias in the second and larger sub-group (ii)—due in the main to a deficiency in the supply or assimilation of iron—do not respond to such therapy, but require adequate and massive iron therapy. This group contains the microcytic hypochromic anæmias, such as chlorosis (in male and female), simple achlorhydric anæmia, the Plummer-Vinson syndrome of dysphagia with anæmia, and the microcytic anæmias obviously secondary to pregnancy,

cancer, gastro-intestinal operation (gastroectomy, gastroenterostomy), nutritional anæmias of infancy, starvation. For purposes of treatment the anæmias of group (a) may also be included in this group.

From these remarks it will be appreciated that the great majority of anæmic patients seen in general practice have either a macrocytic hyperchromic anæmia (with high colour index) or a microcytic hypochromic anæmia (with low colour index); the first group requires the anti-anæmic principle as found in liver or stomach, while the second requires iron.

Treatment of macrocytic hyperchromic anæmias

The successful treatment of the anæmias in this group (i.e., usually uncomplicated pernicious anæmia, or less commonly 'pernicious' anæmia of pregnancy) depends entirely upon the three following important factors: (a) the use of an active anti-anæmic preparation; (b) a full and adequate dosage; (c) a palatable and cheap preparation. The anti-anæmic preparations used are mainly fresh, uncooked liver or stomach, or their extracts, administered orally, while liver extracts are now available for administration by the intramuscular route.

Liver.—Fresh raw liver is still used by some, but the dose required in most cases is at least $\frac{1}{2}$ to 1 lb. or more daily. This for most patients is both impossible and nauseating, and hence insufficient amounts are consumed with inevitably unsatisfactory results. A large number of more palatable liver extracts for oral use are available, but, as they are very expensive, an insufficient dosage is consequently taken. Since some activity is lost in manufacture it is important to bear in mind that if it is desired to administer liver extract in place of $\frac{1}{2}$ lb. fresh liver, then the extract derived from about 10 oz. should be given. It is usually necessary to administer the hydrochloric acid and pepsin mixture (see below) with liver therapy, since the latter does not entirely relieve the gastro-intestinal symptoms. There is no doubt at all that for the treatment of pernicious anæmia the use of fresh liver or oral liver extracts does not give as good results as those obtained with stomach preparations or parenteral liver extracts and is even less satisfactory when the spinal cord is involved.

Stomach.—The value of stomach in the treatment of pernicious anæmia, and 'pernicious' anæmia of pregnancy, especially when combined degeneration of the cord is also present, has now been amply demonstrated in many hundreds of cases. The fresh, uncooked stomach may be given in 4-oz. doses daily, but as this is unpalatable to many patients active desiccated preparations, such as 'pepsac', may be employed with advantage. The initial dose should be not less than 1 oz. (approximately three tablespoonfuls), and this full dose should be maintained until the blood count has returned to normal or, if cord changes are present, when these nervous symptoms have gone.

When the blood count reaches, and has maintained, a count of 4.75 to 5.75 million red blood cells with hæmoglobin values of 90–110 per cent, and there are no signs or symptoms of spinal cord involvement, then the dose can be safely reduced gradually (controlling the progress by regular blood counts), but it is wise to maintain a small regular dose indefinitely according to the requirements of the particular individual. It is possible to discontinue treatment in some cases for short variable periods, but very careful control should be kept on the blood condition. If the red blood-cell count falls below 4.25 millions, treatment should be immediately recommended or the dose of stomach increased, especially when infections or complications arise owing to the rapidity with which these cases relapse once they start on the down grade; the ever threatening possibility of subacute combined degeneration of the cord will not permit of undue liberties in treatment. It is important to realize that even slight infections, such as colds and septic processes, will have profound effects on the blood condition; at such times

the dose of whatever anti-anæmic preparation is being used should be increased to the full amounts temporarily.

Desiccated hog's stomach is readily administered in a variety of ways to suit the patient's palate, always provided that heat is carefully avoided, since the stomach active principle is very sensitive to such form of treatment. Most patients prefer to take it mixed in water (flavoured with condiments if desired), milk, port, burgundy, cold beef extract or soup and other cold drinks, or else mixed with butter, potted meat, sardines and similar foods. The response to adequate treatment with an active product is very characteristic. In the course of seven to twelve days the reticulocytes in the circulating blood will have shown a rapid increase in numbers, reaching a peak or crisis of 30 to 70 per cent, according to the initial level of the red cell count—the lower the initial count the greater the peak. From this time onwards the blood count begins to rise rapidly, although the patient will have shown and felt marked improvement often days before this is noted.

Intramuscular and intravenous liver therapy.—It occasionally happens that a patient with pernicious anæmia may refuse to take oral therapy, the gastro-intestinal symptoms, such as vomiting and diarrhoea, may be considerable, or the condition may be so severe and the blood count so low that more urgent treatment is necessary. Excellent results can then be obtained by the use of a suitably chosen liver extract prepared for intramuscular or intravenous injection, and it is abundantly clear that this method is far superior and safer than even blood transfusion, especially when the red cell count is much below 1,000,000 per c.mm. Since these preparations are likely to be used upon extremely ill patients it is absolutely essential that only such products should be used that are guaranteed by the manufacturers to have been clinically tested and shown to be active in the treatment of pernicious anæmia. This is of extreme importance, since so many of these products are quite useless, while price is no indication of value. [The equivalence of these products in terms of fresh liver varies with the different makes: thus, in two English preparations, 1 c.cm. of extract has been made from 10 grams (preparation A) and 20 grams (preparation B), respectively, of fresh liver, but their actual potencies are so great that clinically they give better results than many kilograms of fresh liver or its equivalence in liver extract orally.] The dose to be employed of course varies with the particular brand, but considering preparation A referred to above, which is guaranteed to be clinically potent, I find that the following gives extremely satisfactory results: According to the severity of the condition, 4–8 c.cm. (representing 40–80 grams of fresh liver) are given on the first day, and 4 c.cm. on each of the second and third days. If the case is one of pernicious anæmia and there are no septic or infectious complications, the patient will begin to respond within two or three days, and the blood count will show extremely rapid increases in the red cell count and hæmoglobin percentage. Of course, even quicker improvement can be produced by slightly increasing the above doses. In most cases of pernicious anæmia the blood will return practically to a normal level without further treatment. Control by means of regular weekly or fortnightly blood counts in the beginning enables a careful check to be kept on the progress—as soon as the red cell count shows signs of flagging a further 2–4 c.cm. of the intramuscular preparation should be given. It will be found that when a normal blood count has been reached the injections will be less frequently required, but here again the necessary dose and frequency depend upon and vary with each individual and, amongst other things, the season of the year. In many cases I find that about 2 c.cm. every two to six weeks sufficient. Since this treatment must be continued indefinitely, a more satisfactory method may be to give the initial treatment as above and then as soon as possible commence the administration of say $\frac{1}{2}$ oz. of pepsac, gradually increasing

to 1 oz. as the patient improves under the influence of the intramuscular liver; the latter then being discontinued, the patient continues with an adequate maintenance dose of this desiccated stomach preparation. Under this regime extraordinarily good results have been obtained, while the cord changes have benefited most satisfactorily.

Cost and potency.—The cost of these different forms of treatment shows enormous variations. Thus, fresh liver in daily doses of 8-16 oz. (and the latter may be inadequate) will cost 8d. to 1s. 10d. per day, while fresh stomach in equivalent dosage only costs 3d. to 1d. Liver extracts are far more expensive, and in sufficient dosage (bearing in mind that it has to be continued indefinitely—probably for life) may require a daily expenditure of 1s. 8d. to 6s. 5d. Preparations of stomach also show enormous variations between 8d. and 4s. 10d. for a dose of 1 oz. daily. Price is no criterion of anti-anæmic potency, and fortunately most of the cheapest preparations are more active than many of the most expensive ones. It is important to realize that not only is the hog's stomach treatment much more efficient than oral liver or liver extracts, especially when cord changes are present, but a consideration of the above figures shows that it is infinitely cheaper. For example, it is easily possible to keep the majority of the patients in normal health on maintenance doses of less than 3.5-7.0 grams of pepsac costing less than 2d. per day, whereas the full daily initial doses of 1 oz. only cost 8½d., as against from three to nine times that amount daily if liver extracts are used. It is possible that the intramuscular liver preparations may be even cheaper, but it is too early as yet to be certain of this. This should have an important bearing on the cost of treating panel patients.

Of greater importance than the cost are the hæmopoietic potencies of the preparations used. It is important to realize that these various anti-anæmic products vary enormously in clinical value; the only way to test them is by specially controlled tests on selected cases of pernicious anæmia under observation in hospital and consequently many preparations are being offered for use without previous trial as to their actual hæmopoietic potencies; thus it is possible that cases considered to be resistant to treatment have really not been given any anti-anæmic principle at all. The more chemical manipulation that takes place in their manufacture the greater is the destruction of the active anti-anæmic principle so that, whereas active stomach and liver products are readily made, parenteral liver preparations are not so easy. In the latter case, therefore, every batch should be clinically tested. Until such time as all preparations are controlled it will be wise to use only such products as are guaranteed to be hæmopoietically active after clinical trial on each batch before issue.

The use of hydrochloric acid.—Sore tongue, vomiting, nausea, indigestion, flatulence, and diarrhoea are some of the commonest and most distressing symptoms occurring in pernicious anæmia, and frequently in other anæmias. As the blood picture of the patient improves with treatment, these are often very much relieved, but there is a marked tendency for the flatulence and indigestion to persist when liver is employed—while it may even increase the symptoms in some cases. Rapid relief is readily obtained by the use of the following mixture:—

Rx Acidi hydrochlorici diluti	. 3ss.
Syrupi aurantii	.. q.s.
Glycerinum pepsini (B. P., 1914) ad	℥ii.
Fiat mistura.	

Sig.: One to two teaspoonfuls in a tumbler of water to be taken with each meal.

This, however, is usually unnecessary when active stomach therapy is used, on account of its strong peptic activity and acid reaction.

Treatment of microcytic hypochromic anæmias

In this group the main deficiency is iron. This is frequently accompanied by achlorhydria gastrica. Satisfactory treatment here requires a full mixed dietary, to which must be added massive doses of iron in a suitably active form. A very large number of iron preparations have been employed, many of which are quite useless. The best and quickest results are undoubtedly obtained by using ferrous salts. Unfortunately they do not keep very well and are rapidly oxidized to the less active ferric salts. The most convenient preparations are: (i) ferrous carbonate or chloride, the former in the form of Bland's pills, which must be freshly made and are better given crushed up immediately before use; the effective dose of Bland's pills is 15-25 grains three times daily; (ii) a scale preparation, such as ferric ammonium citrate, given in a mixture, but this has the rather larger minimal effective dosage of 25-30 grains three times per day. No ill effects arise from the use of even much larger doses of these products and, contrary to the usual belief that constipation ensues, one finds that the bowels become more regular and less troublesome. It is essential that these massive doses should be used for it is a frequent experience that insufficient iron is prescribed with negative results. Of course, the required amount will vary in different patients, but usually it is a waste of time, material and money to give less than 45 grains of Bland's pills or 60 grains of ferric ammonium citrate daily in the early stages.

There appear to be no contra-indications to this form of treatment, even when dealing with patients suffering from the microcytic anæmias of pregnancy, and excellent results follow the administration of large doses of iron. On the other hand, iron preparations for parenteral injection are unsafe to use, since the minimal toxic dose is only slightly greater than the therapeutic one. From time to time suggestions have been made as to the value of copper, manganese, liver and marmite in treatment, but there is no satisfactory clinical evidence that they serve any useful purpose in these microcytic types of human anæmias. In some cases it may be necessary to repeat a short course of treatment on the full dosage of iron from time to time, but the necessity for this will be indicated by the periodical blood counts that will be carried out.

Thus, it will be seen that the broad outlines of treatment of these deficiency anæmias are relatively simple once the diagnosis has been made, but it must be realized that there are borderline or transitional cases where the character of the anæmia may change from a microcytic to a macrocytic type or *vice versa*. The treatment then consists in a careful adjustment, according to the type of anæmia at the time—a simple procedure if carried out in conjunction with regular blood counts.

General treatment

It is important that along with the above specific treatments certain general principles should be followed. Thus, complete rest in bed is necessary in the early stages, since the heart is usually in a weakened, fatty state. Although the patient may feel much better after a few weeks' treatment the cardiac condition will manifestly be unable to tolerate a sudden return to normal bodily activity, as will be obvious by the persistence of dyspnoea and palpation, even with a rapidly improving blood count. A full mixed dietary is a necessary adjunct to treatment and is of special importance since starvation has an adverse and retarding influence. The avoidance of complications and sepsis is of prime importance and vigorous measures must be taken to combat them. Other drugs have been suggested for treatment, but they are best omitted unless there is a definite indication for them, e.g., thyroid gland for any coincident hypothyroidism. There is no justification for splenectomy or the use of arsenic in the treatment of these deficiency anæmias. Blood transfusion is definitely contra-indicated in many

cases and unnecessary in the remainder if adequate treatment on the above lines is carried out.

Scheme for treatment of deficiency anemias.

- (1) Correct diagnosis of the type of anaemia before treatment is commenced.
- (2) Complete rest.
- (3) Removal of cause if found.
- (4) In addition to the general treatment vigorous specific treatment as follows:—

Macrocytic hyperchromic anaemia (e.g., pernicious anaemia)

First day, initial dose of intramuscular liver 6-8 c.cm.*

Second and third days, doses of 4 c.cm. each.

Fourth day onwards, continue treatment with 'pepsae' orally (1 oz. daily).

When blood count has remained at normal and there are no cord symptoms, reduce dose slowly to the

*The dose will depend upon the particular brand of intramuscular liver used. The dose given here is for preparation A, described above, in which 1 c.cm. has been derived from 10 grams of fresh mammalian liver.

necessary adequate maintenance dose (varies with each individual).

If cord changes are present, the 1-oz. dose must be continued without reduction.

Increase to full dose of pepsae if infections, influenza or colds, develop.

Microcytic hypochromic anaemia

If no dysphagia present give the following: Pil. ferri carb. (Blaud's pills), gr. xx, three times daily (ferrous chloride in capsules, or ferric ammonium citrate in a mixture may be substituted).

When the blood count is normal again reduce the dose to a quarter. If the blood count is still maintained in the following months treatment can be discontinued.

When dysphagia is present give: Pil. ferri carb. (as above) crushed up before use, or, better still, ferric ammonium citrate (not less than gr. xxx, three times daily) in a mixture.

If relapse occurs, repeat course of treatment as above.

In both cases hydrochloric acid and pepsin is a valuable adjunct since achlorhydria and gastro-intestinal symptoms are very common in these anaemias.

If the nature of the anaemia changes then treatment must also be changed accordingly along the above lines.

Reviews

FRACTURES.—By P. B. Magnuson, M.D. 1933. J. B. Lippincott Company, Philadelphia and London. Pp. xix plus 466, with 317 illustrations. Obtainable from Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 18-12

THE author of this work is Associate Professor of Surgery in the Northwestern University Medical School, Chicago, and a member of the Fracture Committee of the American College of Surgeons. The latter fact perhaps accounts for a full page list of slogans on the opening page of chapter I, under the heading 'High Lights'.

'Splint 'em where they lie', 'Check frequently with x-rays', 'Watch fixation apparatus constantly', are a few examples from this decalogue. Though sound in precept they are perhaps more suitable, in this form, for a manual designed for the use of nurses and dressers than in a scientific work for surgeons. Apart from this, however, the book is written in an agreeably direct and dogmatic style, as might be expected from a worker of extensive practical experience, and it is refreshing to be able to add that it is clearly a record of personal experience rather than a textbook of many methods culled by the scissors and paste process of extensive reading. There is no bibliography, but this cannot be regarded as any disadvantage to the busy practising surgeon as opposed to the teacher or research worker, and the work is clearly intended for the former.

The text makes easy reading and the language is to the point, but brevity is sometimes carried to excess. The sentence 'Fractures of the patella with separation of the fragments are always operative' while clear as to meaning would certainly meet with criticism in an English book.

A good example of the many practical chapters in the book is to be found in the account of fractures of the skull. The importance of diverting attention from the actual fracture of the bones to the effects on the cranial contents is well emphasized. A section on the mechanism of the circulation of the cerebro-spinal fluid and the part played in lumbar puncture and dehydration methods in the treatment of these injuries is free from all academic matter which might tend to obscure essential points and typical of the precise and assimilable style of the author.

It is unfortunate that the authors of works on fractures should find it necessary to reproduce large numbers of radiographs; many bear reproduction very poorly. Certainly in the reviewer's copy of this book, the large black shadows of the skull, numbered 304 to 308, convey very little of interest or value. The same may be said of several reproductions of films of the tarsus, spine and pelvis. Considerable reduction in the weight of the book would be achieved by a stringent weeding of unnecessary radiographs. In cases where an essentially interesting radiograph is badly a line tracing would be more instructive and undoubtedly clearer. It must be added however that a large proportion of the radiographs are excellent and of real interest, while the pictorial photographs and drawings are of a high standard, serving to interpret the text in the clearest manner. The line drawing on page 251, it should be noted, is misleading. The counterpoise shown attached to the foot is labelled as supporting the weight of the leg and the foot. Surely this is the function of the Pearson cradle frame in which the leg rests. It is correctly depicted in this fashion in the illustration on the preceding page. The counterpoise referred to is usually used to prevent foot drop.

While the author, in the preface, disavows any attempt at dealing with the operative treatment of fractures, several specialized operative procedures, not usually to be found in textbooks on general surgery, are well described and clearly illustrated. These will be welcomed by the man practising away from large centres who is compelled to attempt relief to patients unable to afford a visit to specialists in the larger towns. There must be many such in up-country cities in India.

Special traction appliances for reduction, based on the principle of a Hawley table with perineal pillar, do not appear to be used by Professor Magnuson, and the double inclined plane so much advocated by Bohler of Vienna for fractures of the femoral shaft is not referred to. On the other hand the use of surprisingly simple device for traction during reduction, termed the 'endless loop', is clearly illustrated and deserves to be more widely known.

Although scarcely likely to be used as a textbook by the student reading up fractures, this work is well

adapted as a guide to the junior surgeon on account of its strongly practical outlook. It should not be missed by those interested in injuries of bones, who have already enriched their practical experience by a study of other standard works.

The price is moderate and future editions may be predicted, but the bulk and in consequence the price might be usefully reduced by a careful weeding out of radiographs.

H. R. R.

DEMONSTRATIONS OF PHYSICAL SIGNS IN CLINICAL SURGERY.—By H. Balloy, F.R.C.S. (Eng.). 1933. Fourth Edition. John Wright and Sons, Ltd., Bristol. Pp. xx plus 287, with 335 illustrations, some of which are in colour. Price, 21s.

THIS book was first published in 1927 and in the preface to the first edition the author deplored the modern tendency to rely on laboratory diagnosis to the exclusion of the old-fashioned methods of investigation by the use of the clinician's senses. The model work in this field is Lejar's 'Explorations Cliniques et Diagnostiques', which has since appeared in an English translation, but it is too diffuse and lengthy for the use of the student, whose need for a short manual of methods of clinical examination and the physical signs to be expected in each region of the body are well met by this book. That it is appreciated is shown by the rapidly recurring editions, each of which improves on the last. The changes in the present edition are mainly in the direction of improvement of the illustrations. A beautiful coloured picture of acute lymphangitis of the arm, new illustrations of cases of bronchial and dental cysts, a better picture of Hutchinson's teeth than in the former editions and coloured plates of leukoplakia and carcinoma of the tongue are features of this edition. The section on sub-diaphragmatic abscess has been transferred to the chapter on the thorax and Lockwood's test for chronic appendicitis has been added to the text, though nowadays the surgeon will prefer to rely on the gastro-ileal reflex as demonstrated by the barium meal, a phenomenon which also depends on interference with the mechanism of the ileo-caecal valve. There is a new figure showing palpation of the thickened ureter, but the palpation of the ureteric point on the abdominal wall for tenderness seldom appears in English textbooks, though always given by French writers. There is a new section on gangrene with several nice figures, but it is regrettable to see that the author still adheres to the view that thromboangiitis obliterans is only to be expected in Russian Jews.

These are the main changes in an edition which has enlarged by 15 pages and 30 illustrations and has improved thereby, though it still keeps its character of a 'tipster', which means a disjointed style but perhaps accounts largely for its popularity with students, to whom, as formerly, it can be strongly recommended.

W. L. H.

THE CURE OF HÆMORRHOIDS, VARICOSE VEINS AND ULCERATION, AND ALLIED CONDITIONS: BY MODERN METHODS OF INJECTION AND BANDAGING.—By Stuart McAusland, B.A. (Lond.), M.D., Ch.B. (Liv.). 1933. John Bale, Sons and Danielsson Ltd., London. Pp. 63, with 11 plates. Price, 3s. 6d. net

THIS modest work is intended to be a guide to the general practitioner in the art of non-operative treatment of varicose conditions and as such it fulfils its object very well. The descriptions of technique are clear, the necessary instruments are illustrated and the contra-indications for this form of treatment are very carefully explained. For hæmorrhoids the author prefers the almond-oil-carbolic mixture on the grounds of the absence of sloughing, the reduced number of injections necessary and the absence of hæmorrhage and post-operative discomfort. The reviewer, having

some experience of this technique, can entirely agree in his preference. In a thousand cases the author has had only one ischio-rectal abscess and two thromboses. It is often erroneously supposed that injection causes thrombosis and so obliterates the piles, but its real action is to set up an aseptic inflammation. For varicose veins the author prefers quinine urethane and gets 85 per cent of permanent cures, though he discusses the use of the other solutions. He prefers to start above and work down, which is contrary to the usual practice. The question of whether recurrences are recanalizations of obliterated veins or varicosities of fresh veins has lately been the subject of discussion; the author favours the latter opinion and thinks they are mostly due to neglect of after-treatment. Some brief notes on injection treatment of other conditions conclude a very practical little manual.

W. L. H.

BICKHAM'S OPERATIVE SURGERY.—Seventh volume, 'The newest operations'. By Warren Stone Bickham, M.D., F.A.C.S., and Calvin Mason Smyth, Jr., M.D., F.A.C.S. 1933. W. B. Saunders Company, Ltd., Philadelphia and London. Pp. 849, with 765 illustrations. Price, 55s.

THE final volume of Bickham's 'Operative Surgery' has been written by Dr. Smyth as a supplement to the preceding six volumes and includes an index to the complete work. It summarizes the advances which have occurred in the field of surgery during the eight years that have elapsed since the publication of the previous volumes, bringing all the sections up to date. New operations are described, omissions from the previous volumes rectified, and changes in attitude to the older procedures considered.

The high standard of illustration and general presentation of the previous volumes has been maintained. The text is concise and a short commentary follows the description of each new operation. The sections on surgery of the colon and thorax are particularly well and fully dealt with, these being the regions in which the greatest number of new operative procedures have been devised. Gynæcology is included, perhaps a little unwisely in a work on general surgery.

Though chiefly of interest to possessors of the preceding volumes, this final volume is a self-contained record of recent progress in operative surgery and can be recommended to those who wish to add a modern supplement to other works on the subject.

J. C. D.

MODERN ASPECTS OF GASTRO-ENTEROLOGY.—By Dr. M. A. Arafa, M.R.C.P. (Lond.). 1933. Baillière, Tindall and Cox, London. Pp. xviii plus 374, with 79 illustrations. Price, 27s. 6d.

A few years ago an exploratory laparotomy was an operation of common occurrence. Its rarity to-day in well-equipped hospitals is striking testimony to the progress which has been made in the diagnostic fields of gastro-enterology. This book brings together the clinical, radiological, chemical and optical methods of investigation of abdominal disease in which recent progress has been made, within the compass of a volume of reasonable size.

The author was given three years' study leave by the Egyptian Government and spent the period in visiting various English and Continental clinics. He had unrivalled opportunity to hear the views of many authorities and to compare and summarize their methods. Although his work is largely a compilation it is of value in that few medical men have the time or knowledge of languages to undertake such a task.

The text is systematically arranged and illustrated by original drawings and well-chosen radiograms. The style is clear, though one is a little irritated by the frequency with which proper names are quoted as references to relatively unimportant facts. This minor criticism, however, does not detract from the practical

value of the book, which can be recommended to those interested in the diagnosis of alimentary disease.

J. C. D.

INFECTIONS OF THE HAND.—By Allen B. Kanavel, M.D., Sc.D. Sixth Edition. 1934. Baillière, Tindall and Cox, London. Pp. xvi plus 552, with 216 figures. Price, 30s.

SURGEONS familiar with the earlier editions of this classical monograph will find much new matter in the current edition. The book is about half as large again as the fifth edition which appeared in 1925 and the price has been advanced from 25s. to 30s. It is nevertheless well worth the outlay, and a junior surgeon entering on an operating career will sooner or later have reason to congratulate himself should he take the trouble to read and digest its contents. That the book during two decades should have reached its sixth edition speaks well for the spread of correct notions on treatment in this difficult and, until recently, disappointing branch of surgery. None who have had experience of hospital surgery will be disposed to question the claim put forward by the author that we may expect a restoration to complete function in 95 per cent of the cases with abscesses of the fascial spaces of the hand by careful diagnosis, properly placed incisions, and efficient after-treatment. The principles underlying these factors are taught in this book with a thoroughness which makes it a model of clinical research based on sound experimental anatomy.

The new matter includes much interesting information on human bites and injuries from teeth, metacarpophalangeal joint infections, gangrenous infections, injuries from indelible pencils, cattle hair and other peculiar infections. Special chapters have been added dealing with the functions of the hand, the use of splints, and the prophylactic treatment of injuries. Every chapter has been revised and the changes almost constitute it a new book.

The subject-matter is divided into four parts and it is a distinct advantage to find collected in part I a full account of general principles and details of the anatomical researches on which Professor Kanavel based his teaching nearly twenty years ago. This makes for easier reading than in the earlier editions where pathology and treatment were often mingled with difficult anatomical detail. Few medical men are likely to forget the stress laid in their student days on the surgical importance of certain fascial planes and spaces in the body. Septical minds with a leaning towards medicine rather than surgery have been known to dub them artifacts produced by the skill of the dissector rather than as having any real existence in the living. The deep cervical fascia, Colles' fascia and the pelvic fascia, with other well-marked lines of cleavage and spaces in the body, were however first described by surgeons and not by anatomists. We owe to Kanavel the knowledge that the special fascial spaces of the hand merit as much attention in the teaching of anatomy as those in other parts of the body. These spaces now receive their due attention in modern textbooks of anatomy, but the student will look in vain for an adequate treatment of them in the standard textbooks of London and Edinburgh of twenty years ago. The reader will do well therefore not to shirk the first 150 pages if he desires to follow and master the clinical and pathological matter of the later chapters.

Part II deals with localized infections and special morbid processes as affecting the hand, such as anthrax, syphilis, chronic infections and gangrenous infections, etc., while in part III we find those important conditions, lymphangitis, major fascial space infection and tendon sheath infections which unfortunately sometimes menace the arm if not the life of the patient when the treatment is not based on sound teaching.

Part IV, which deals with complications, sequelæ, and after-treatment will be of special interest to surgeons connected with railways, factories, and mills, in view of the increasing importance and extension of the

provisions of the Workmen's Compensation Act now operating in India. Much interesting discussion will be found in regard to the 'position of function' of the hand. It is scarcely an exaggeration to say that, here in India at least, the principle of conserving the maximum possible function by suitable posture during treatment is too often overlooked. The author's words will bear quoting on this point. 'The hand should never be simply surrounded by hot dressings and permitted to lie in an extended position. It should be maintained in dorsal flexion at the wrist at an angle of 45 degrees; the phalanges at the metacarpophalangeal joints should be flexed to the same angle and, most important, the thumb should be abducted from the palm, adducted towards the ulnar side of the hand and rotated so that the flexor surface of the thumb is opposite the flexor surface of the index finger'. The repeated exhortations in the use of the 'cock-up splint' of student days are usually well remembered in fractures and injuries of the arm, but too often forgotten in the treatment of infections of the hand.

A valuable feature of this closely reasoned and by no means easy work to read is the author's practice of supplying a short résumé in dogmatic terms at the end of some of the more difficult sections. The general get-up of the work is excellent. The book is printed in America and the illustrations are without exception of the high standard we have learned to expect in American medical publications.

H. R. R.

THE SPREAD OF TUMOURS IN THE HUMAN BODY.—By R. A. Willis, M.D., B.S., D.Sc. 1934. J. and A. Churchill, London. Pp. x plus 540, with 103 illustrations. Price, 25s.

THAT the study of the spread of malignant tumours in the human body is a matter of great importance, one would say was quite obvious; yet it is surprising that hitherto no serious attempt has been made to collect this information into book form. This fact alone supplies ample justification for the publication of this book; however, the writer has not only produced a valuable critical review of the subject but has added his own experience in 323 autopsies on cases of malignant disease. These were not mere routine autopsies, but must have been conducted in a most painstaking manner, if they are to be judged by the reports of his findings that form the appendix of the book.

The usual procedure in books on pathology has been imitated and the subject-matter has been divided into two parts which might be labelled, respectively, 'general' and 'special'; part I contains a number of chapters on the different modes of spread of tumour, direct extension, by the lymphatics, by the blood, etc., it includes a chapter on experimental oncology in animals, and concludes with an extremely interesting chapter on the susceptibility of different tissues to metastasis. The author does not believe that the spread of tumours can usually be explained on a mechanical basis, as has been claimed by some workers; here we are in complete agreement with him. Part II consists of chapters each devoted to secondary growths in one special organ or tissue. There is an appendix, to which reference has been made, and a very extensive bibliography.

The book, which is very beautifully produced and contains many very excellent plates, photographs and photomicrographs of tumours, is a most important publication from the point of view of the surgeon, the pathologist and the cancer research worker.

A TEXTBOOK OF MEDICINE.—By American Authors. Edited by R. L. Cecil, A.B., M.D., Sc.D. Third Edition. 1933. W. B. Saunders Company, Philadelphia and London. Pp. xlv plus 1664. Price, 42s.

Writing a book on general medicine in modern times necessitates more than one author undertaking the work, because no one man can write authoritatively on the immense field covered. But the employment of

the one hundred and forty-one contributors who combine in the production of the book under review is rather overdoing the usual practice of to-day.

The multiplicity of authors leads to a very disjointed presentation of the subject that was lacking in similar books of thirty or forty years ago which were written by only one or two authors. An especially striking example of the disadvantage of too many authors is seen in the section on pulmonary tuberculosis to which five different persons have supplied subsections.

The arrangement of the book is also somewhat confusing for the word 'infectious' has apparently been used in its widest sense, as all diseases caused by parasites whether bacterial, filterable, mycological, protozoal or helminthic have been placed together in this section, irrespective of whether the diseases are directly contagious, infectious or need one or more intermediate hosts for their propagation. Although a rough classification of the causal organisms has been followed in arranging this unwieldy group of diseases certain surprises occur when turning the pages; for instance, infection with *Balantidium coli* is separated from the recognized protozoal diseases by those caused by the spirochaetes (*sensu lato*) and is found sandwiched between yaws and trematode infections. Another unsatisfactory condition that arises from this method of grouping is shown by the following example which could be indefinitely multiplied. There is a section headed 'Diseases of the Respiratory System' but the pneumonias and pulmonary tuberculosis are in the infectious section, while tuberculous laryngitis as well as all forms of bronchitis come under the respiratory system. Such a grouping makes the book very difficult to use as it means constantly turning from one part to another.

With so many authorities engaged in the preparation of this work one would not anticipate that there would be any omissions, nevertheless no mention of atabrin appears in the treatment of malaria, and in the same section the treatment of blackwater fever is discussed in four and a half lines devoted to the pros and cons of quinine treatment without any mention of suppression of urine and the danger of heart failure, two of the main things to guard against in this disease.

On p. 420 we note a heading in black type 'South African Trypanosomiasis' and bracketed beneath it in italics 'Chagas' disease'. Then follows a brief but adequate description beginning with the words 'South American trypanosomiasis or Chagas' disease.....'. The heading of course is an oversight in proof reading, but one calculated to confuse the novice in tropical medicine, and to shake the faith of anyone who might use this book for an authoritative statement on a subject with which he is unfamiliar.

Although there is much sound and well written matter in this book the above one or two criticisms will indicate that as a whole it is capable of considerable improvement.

When one turns the last page and lays down the book one wonders if the immense amount of time that must have been spent in its production has been worth while, because it occupies no vacant niche in the vast edifice of medical literature. It in no way replaces the older standard one-volume textbooks of medicine that have been kept up to date after the death of their original authors and in spite of the many alterations, omissions, and additions that have been made in subsequent editions still maintain that indefinable quality of continuity they acquired, being written as they were usually by one man; such a quality is entirely lacking from a volume such as we have just reviewed.

From this thought we are led a step further and that is to wonder whether the publication of medical literature as a whole is not suffering from the same disabilities of overproduction such as are tea and rubber for example, and whether the appointment of an international restriction committee on production in medical literature might not enhance the value of its products,

in the same manner as the value of the above commodities is being increased by this means.

P. A. M.

DISEASES OF THE CHEST AND THE PRINCIPLES OF PHYSICAL DIAGNOSIS.—By G. W. Norris, A.B., M.D., and H. R. M. Landis, A.B., M.D., Sc.D. 1933. Fifth Edition. W. B. Saunders Company, Philadelphia and London. Pp. 997, with 478 illustrations. Price, 50s.

We welcome the fifth edition of this well-known book, which still maintains its popular position in English-speaking countries. The first edition appeared in 1917 and the fact that the fifth edition is available only 16 years after is evidence of its popularity and of its keeping abreast of the times.

The book is thoroughly revised and enlarged, and runs to nearly a thousand pages. There is hardly anything omitted. It is written principally for the clinician and, as the authors have rightly observed, 'Clinicians would do well to remember that the laboratory should be their partner and not their master'.

The book has been divided into four parts. The first two parts deal with the examination of the lungs and of the circulatory system and have been written by G. W. Norris. Separate and exhaustive chapters have been written on inspection, palpation, percussion and auscultation, and their importance shown in the examination of patients. Part III deals with the diseases of the bronchi, lungs, pleura and diaphragm, and part IV with the diseases of the pericardium, heart and aorta. These parts have been written by H. R. M. Landis.

Two interesting chapters have been added:—(1) By C. M. Montgomery, on the transmission of sounds through the chest, and (2) by E. B. Krumbhaar on electrocardiograph in heart disease. The first deals with the fundamental principles involved in the transmission of sounds from within the respiratory tract to the chest surface and the principles discussed have been applied to six typical chest conditions, namely, normal lung, partially collapsed lung, solid lung, pleural fluid, pulmonary cavity, and pneumothorax. The other chapter shows the importance of the electrocardiograph in the progress and treatment of heart disease. It shows how repeated records give valuable information in several ways about the course of the disease and the response of the heart to digitalis.

A brief account of the part played by the bronchoscope in the diagnosis of respiratory affections is also given and is written by L. H. Clerf. The importance of bronchoscopy is evident from the following quotation of Chevalier Jackson—'The internist can tap, look and listen on the outside; the roentgenologist can look through the patient. Add to these the bronchoscopist who can look inside the lung, and we have a tripod on which to base our diagnostic studies, and there would be fewer cases in which a positive diagnosis could not be reached'.

It is difficult to summarize the main features of the book in which everything is already written in a compressed form. The book is copiously illustrated and contains 478 figures of which 4 are coloured plates, and several are photographs of frozen sections from the cadaver, previously hardened in formalin, in order to retain the anatomic relations of the tissues as during life. These will be found to be of great help to the readers. A very exhaustive index is given at the end of the book.

In the opinion of the reviewer, no better book than this could be recommended to those who want to make diseases of the respiratory and circulatory systems their speciality. It may also be recommended to general practitioners who wish to keep their knowledge of these systems up to date. The book is well written, and the printing, illustrations and general get-up are excellent.

Y. G. S.

HUMAN EMBRYOLOGY AND MORPHOLOGY.—By Sir Arthur Keith, M.D., F.R.S., LL.D., D.Sc., F.R.C.S. (Eng.). Fifth Edition. 1933. Edward Arnold and Co., London. Pp. viii plus 558. Illustrated. Price, 32s.

This edition is a distinct advance on its predecessor for by careful selection of the mass of fresh knowledge that is constantly being added to the science of embryology the author has added about sixty pages to the book and increased the number of chapters by two. But when one considers the amount of matter that has appeared on embryology since the first edition of this book was published it is remarkable that it has been kept comparatively short. This has not been done by omission of essentials, but by careful selection and condensation of all the important facts. The book contains 535 figures many of which comprise two or more separate drawings so that the actual number of illustrations is probably nearer 700. Many of these are original, but a considerable proportion have been drawn from other sources and all of them are of value. Constant reference to the figures is necessary to understand this difficult subject and they have been so carefully arranged that one usually finds a figure on the same page as the points, which it illustrates, are described. This adds greatly to the ease and pleasure of reading the book, for there is nothing more annoying and distracting in reading a difficult subject, than to have constantly to turn backwards or forwards for many pages to find a figure referred to in the text.

In the preface, Sir Arthur Keith almost apologizes for having departed in subsequent editions from what he describes as his 'utilitarian ideal' which governed the preparation of the first edition.

He means that he has added facts which at the time of writing perhaps have no clear clinical application, but as he rightly says, 'Who can tell what the clinical utility of any newly discovered fact may prove to be?' The reviewer considers this apology unnecessary, for the wider view of the subject that these added facts give greatly assists in understanding the whole, because, although somewhat dimmed by time, he still has a lively recollection, as an undergraduate, of wrestling with the first edition of this book about a year after it was published, and he finds the present edition much easier to follow.

This is a book that should be carefully studied by all serious students of medicine and surgery for nowhere will they find better presented the numerous facts about the development of the human body that are essential to a full understanding of many of the clinical manifestations of disease.

P. A. M.

PRACTICAL POINTS IN EYE SURGERY AND DRESSING.—By H. E. Jones, M.R.C.S. (Eng.), L.R.C.P. (Lond.). 1933. John Bale, Sons and Danielsson, Ltd., London. Pp. 27, with 3 tables. Price, 2s. 6d.

THIS little volume was not meant to be a cram book, nor in any way a substitute for a textbook on the subject, but was written as a practical guide to nurses, dressers, house surgeons, and general practitioners. It fulfils its function admirably. Probably the most useful part of this very useful little book is the three tables which will be found in an envelope at the end of the book; they are mounted on canvas to ensure long wear, if the reader prefers to keep them in the book, but they are just the kind of table that should be mounted and hung up in the surgery or operating ante-room.

They refer respectively to 'urgent non-traumatic cases', 'common eye injuries', 'operations'; the first two give the points of diagnosis and immediate treatment, and the third the method of preparation required, the instruments used, instructions to the patient, etc. It is an eminently practical book that we can thoroughly recommend.

AN ELEMENTARY HANDBOOK ON RADIUM AND ITS CLINICAL USE.—By D. F. Clephan and H. M. Hill. 1933. Oxford University Press, London. Pp. 164. Illustrated. Price, 7s. 6d.

To the unscientifically-minded public radium is little more than a name of some substance that has wonderful medical and other properties; it is usually associated in their minds with x-rays, if not with 'radio' sets. The medical man usually has clearer ideas on the subject, but even he, unless he has made a special study of the subject, is a little vague about the properties of radium except that it is used in the treatment of cancer, and that it is dangerous stuff to handle. To this latter class of readers the book under review will have a particular appeal.

The book is written by two radium officers of many years' experience at two institutions in London where radium is extensively used in the treatment of cancer and other conditions; it tells in simple scientific language all that the general practitioner, the medical student, and the nurse or the technician in a radium department, will want to know about the origin, the nature, the properties (both physical and therapeutic), the care of, and the technique of the application of radium and other radio-active substances.

The subject is dealt with clearly and concisely, and the authors have not allowed themselves to wander beyond the scope of the book. We have no criticisms to offer except that the time period of thorium is given as a hundred and thirty thousand million years in one place and as 13,000,000,000 in another; time, however, will show which is correct. There is a useful list of references at the end of each chapter. The publishers have produced a neat little volume at a very reasonable price.

VACCINE THERAPY IN ACUTE AND CHRONIC RESPIRATORY INFECTIONS.—By H. T. Gillett, M.D. (Lond.). 1933. H. K. Lewis and Co., Ltd., London. Pp. xii plus 104, with 9 charts. Price, 5s.

THE employment of vaccines in pneumonia and in any acute infection is difficult to justify on theoretical grounds; it is very necessary, therefore, that claims for their value in practice should be carefully scrutinized. The author's claim for the practical value of vaccines in pneumonia rests mainly on a series of cases treated by the writer of the foreword to the book. It seems improbable that given judiciously vaccines will do much harm in pneumonia as long as they are used only in cases where serum was not available for some reason or other; if, therefore, this book stimulates others to give a trial to this form of treatment and to help to settle whether or not it is of value, the book will have served a useful function. There is, however, not much more that we can say in favour of it.

The author's theoretical argument in favour of vaccines in pneumonia, which is roughly that the stimulation of the local reticulo-endothelial cells in the skin tends to produce just a little more anti-toxin and that every little helps, does not sound very strong, but we know very little about immunity as yet, and in the past many much more improbable theories have proved to be right.

The author is an advocate of small doses, and the following sentence appeals to us more from a medical than from a grammatical point of view:—'Contrary to expectation, it appears that large doses of vaccine given prophylactically do not necessarily produce a higher immunity than when small doses are given'. On the subject of influenza, the author who has his own rules of nomenclature says 'the bacillus influenza (B. Pfeiffer) is apparently not always found' and expends a number of pages of this very small book on discussing—not very authoritatively—the aetiology of the disease. We would refer him to the 640-page monograph on this subject issued by the Pickett-Thompson laboratories.

In the section on the technique of vaccine administration he wastes some lines on describing what is

universally known as a tuberculin syringe, he displays considerable optimism over the subject of sterilization, and fails to mention whether the vaccine should be given intradermally, subcutaneously, intramuscularly, or intravenously.

THERAPEUTIC USES OF INFRA-RED RAYS.—By Annandale Troup, M.C., M.B., Ch.B. (St. And.). Second Edition. 1933. The Actino Press, Ltd., London. Pp. 90. Illustrated. Price, 6s. 6d.

THE reviewer did not have the privilege of seeing the first edition of this useful little book, but he gathers that the present edition is rather fuller than the first, though its form is much the same. Dr. Troup is a worthy champion of the infra-red rays; he thinks that the harmful effects attributed to them are often exaggerated, and he does not think that their value as a therapeutic agent has been sufficiently appreciated, the credit due to them often being claimed for other associated rays.

The book is essentially a 'primer' on infra-red rays; it tells in simple words all the medical man needs to know about them—their place in the spectrum, their physical properties, the methods by which they can be applied, their therapeutic indications, and their contra-indications. Their most important use is the alleviation of pain and the curing of painful conditions.

The simplicity of the book does at times border on naïveté, as in the following quotation:—'Infra-red rays, if administered in the form of general infra-red radiation, bring about a marked decrease of the white blood (leucopenia). They have therefore been used successfully in the treatment of leucæmia. Conversely, they should not be used in the treatment of a patient with a low white-cell count'.

To anyone with a strong feeling in favour of uniformity, the practice of printing 'I. R. radiation' on one line and 'infra-red radiation' on the next will not appeal; the abbreviation of so short a word is, in any case, hard to justify.

In order not to close on a querulous note let us repeat that this is a very practically useful book, and that we can recommend it to the practitioner.

A TRANSLATION OF 'MIDWIFERY FOR NURSES'.—By Russell Andrews (Telugu Edition). 1933. The Christian Literature Society for India, Madras. Pp. 269. Illustrated. Price, Re. 1-8

THE Christian Literature Society for India have undertaken the translation into the vernacular of the well-known book of Russell Andrews' 'Midwifery for Nurses'. Up-to-date textbooks in the vernaculars for pupil-midwives are not available, and the society, in endeavouring to place this book before the nurses, has taken pains to see that the translation has been done in an easy style which permits of its being easily understood. The book is got up neatly, with a few diagrams here and there. It is up to date and should prove of great value to midwives under training. The translator has done well in incorporating some of the technical words in the English language without a laborious attempt at translating them. This makes it easier for pupils to follow the class lessons and the day-to-day practice.

The book deserves a place in all teaching institutions where midwifery is taught in Telugu.

A. L. M.

EXTRACTION OF TEETH.—By F. Coleman, M.C., L.R.C.P., M.R.C.S., L.D.S. 1933. Third Edition. H. K. Lewis and Co., Ltd., London. Pp. vii plus 232, with 131 illustrations. Price, 12s. 6d.

CHAPTER I deals with extraction of teeth by what may be termed classical methods. Many valuable hints and examples are given: the author emphasizes the very true fact, that a tooth should be 'played' rather than subjected to force, especially sudden force without reference to the natural paths of least resistance.

Chapter II deals with difficulties and complications, this chapter deserves careful study.

Chapter III is on anaesthetics. It is to be regretted that the directions for injections are not given in more detail.

Chapter IV deals with surgical extractions and modern methods of diagnosis and treatment. If these methods are intelligently applied it will go far to make the difficulties and complications of extractions a thing of the past.

E. H. B.

CONSTITUTION AND HEALTH. PSYCHE MINIATURES. GENERAL SERIES. NO. 60.—By Raymond Pearl. 1933. Kegan Paul, Trench, Trubner and Co., Ltd., London. Pp. 97. Illustrated. Price, 2s. 6d.

RAYMOND PEARL is a biologist, and as such claims it as 'his inalienable right to study man, the most interesting of all animals'. He goes further, he assumes the right to criticize the physician on his own ground, in his attitude towards disease as exhibited in that most aberrant of animals, man. It would be churlish to grudge him his right which he has most assuredly earned by the assistance that he has already rendered to medical science; few medical libraries worthy of the name have no copy of *Medical Biometry and Statistics* on their shelves.

Though we do not grudge him the right to criticize, we do not entirely agree with his criticism. For example, we do not think that his estimate of the attitude of the average physician, as viewing disease as something separate from man, superimposed on a normal individual, attacking and invading the healthy body, and not as an aberrant reaction of the constitution, is correct; it may have been true of the physician of 20 years ago when the bacteriological phase of medical philosophy was at its height but not of the physician of to-day. Nor does he act on this principle in the majority of cases; even when he employs so-called specific treatment, he does not picture the 'invaders' as being knocked out one by one by the drug he is giving—but perhaps we are taking the argument too far; the biological mind does not take much account of treatment.

It is, we hope, needless to point out that we are not criticizing this stimulating little book. It can be read comfortably at one sitting, but its value cannot be judged by its size, as it is of the nature of a catalytic agent, and will excite as much thought as the average thousand-paged textbook.

L. E. N.

THE HISTORY OF MALARIA IN THE ROMAN CAMPAIGNA FROM ANCIENT TIMES.—By the Late Angelo Celli. Edited and enlarged by A. Celli-Fraentzel. 1933. John Bale, Sons and Danielsson, Ltd., London. Pp. vi plus 226. Price, 10s. 6d.

DURING recent years there has been a considerable amount of imaginative writing regarding the part played by malaria in bringing about the downfall of Rome. The author of this book, who has spent his life fighting malaria in the Roman Campagna and who cannot therefore be accused of underrating the importance of this disease, deals with facts, as far as history can be said to provide facts, and does not subscribe to this romantic view of the destiny of this once great empire. The history of Rome, the city, has on the other hand been largely written by the anopheles mosquito. Rome itself has always been comparatively free from malaria, but its compass has been rigorously limited, as every attempt at expansion has had, sooner or later, to be given up; the suburbs of Rome have throughout the centuries seen a series of palaces, built and then abandoned and allowed to fall into ruins. Many emperors and the majority of the popes have made some attempt to deal with the

problem; some of them have had apparent, temporary successes, but in the end they have had to admit defeat. There seems to be little support for the suggestion, obviously made by their enemies, that the popes have deliberately neglected the Roman Campagna so that the miserable condition of this country should form a contrast to the grandeur of the Holy See.

This history is divided into periods—the pre-Roman, the republics, the empire, the early and later middle ages, the modern period, and the latest history, even this last chapter only takes us up to the discovery of the mosquito carrier of malaria; with true Italian courtesy, not always reciprocated, the writer gives the major credit of this discovery to Ross. It is a matter of great regret that Professor Angelo Celli did not live to finish his work. His story of the campaign, which is now being so successfully waged in the Roman Campagna and in the inauguration of which he himself played so strenuous a part, would have formed an invaluable final chapter. The chapter contributed by the editor, his widow, gives us a glimpse at the results that are being obtained, but little in the way of detail as to how this swamp that has defied emperors and popes for twenty centuries is now being turned into a prosperous and fertile country-side.

The book is a most entertaining and scholarly production; it cannot fail to interest the physician, the malariologist, the historian, and in fact anyone who is interested in human welfare. There are about forty pages of references; large numbers of these are to British writers. There is no suggestion that the book is a translation, but it is written in irreproachable English.

L. E. N.

HADWEN OF GLOUCESTER, MAN, MEDICO, MARTYR.—By B. E. Kidd and M. E. Richards. 1933. John Murray, London. Pp. x plus 345. Illustrated. Price, 7s. 6d.

A CRANK has been defined, probably by Bernard Shaw, champion of all cranks, as a person who holds and

acts upon an opinion that is contrary to orthodox teaching, but it is claimed directly he has converted a sufficiently large number of his fellows to his point of view he ceases to be a crank.

This is seldom true, as all worthy cranks have more than one arrow in their quiver. They have made the discovery that the majority is not always right; they assume illogically that the majority is never right, and so oppose all generally-accepted theories. In mediæval days religion provided the best gymnasium for the antics of the crank, but nowadays there is no 'kick' to be got out of religious unorthodoxy and, as his chances of being burnt at the stake have finally disappeared, the crank usually turns to medicine, a vast field in which he can display his perversity almost endlessly.

Dr. Hadwen was the complete crank; he was a disbeliever in the 'germ theory' of disease, an antivivisectionist, an anti-vaccinationist, and an anti-everything that was generally accepted by the medical profession. He caused a great deal of trouble and did much harm, but on the other hand there is no doubt that he did some good; it is very good for the medical profession to have their accepted theories questioned; it shakes their complacency and makes them think. Also there seems to be little doubt that Dr. Hadwen was a sincere, if misguided, man. He had a full life, which extended beyond the allotted span, and a comfortable death. What more could any man, medico, or martyr wish for?

No cause is so forlorn that its champion will not collect a number of disciples; the more forlorn the cause the larger will be the percentage of women amongst these. Dr. Hadwen was always sure of his women supporters, and after his death they have not altogether failed him, but the writers of this biography have not presented a very good case. Had the book ended at frontispiece, which is the photograph of a white-haired, kindly-faced, old man, it would have left a better impression.

L. E. N.

Abstracts from Reports

ABSTRACT OF THE ANNUAL REPORT OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1931

VOLUME II

THE Report contains sections on the Health of the British and Indian Armies in India. Owing to the precision and care which are devoted to the health of these two large bodies of picked men, the report necessarily contains much that is of scientific interest to the general practitioner in India, and also to the scientific medical worker and the hygienist. Some of the more general matters will be of interest to the readers of the *Gazette*.

Malaria continues to be far and away the chief cause of sickness in the British Army in India.

Over 6,200 admissions for malaria occurred in 1931. There are two interesting observations on the 'carrier' question. In Wellington, a hill station hitherto considered to be malaria free, *A. maculipalpis* was found to be the carrier; near Rangoon, which is itself considered to be malaria free, at Mingaladon, infections occur and *A. hyrcanus* was proved to be a carrier there. An investigation into 'missed' cases of malaria showed that only 1 per cent of the total admissions might be considered to be 'missed'—a satisfactory conclusion.

The presence of urobilinuria as an aid to diagnosis in malaria was investigated; the result is as yet indeterminate. The presence of albuminuria in malaria

was shown to be common but of a transient nature. It was not due to the quinine given. As the results of trial a combination of atebirin for 5 and 7 days, followed by plasmoquine in convalescence, seems to be suggested as a cure for the individual attack and the infection.

Annual malarial surveys are being done all over India and much useful information collected. A 'weekly dry day' is proving very efficacious in Kohat and similar places. All artificial collections of water in and around cantonments are dried up for the whole or part of a day each week.

Interesting notes on the treatment of nullahs, on spraying, and on the use of mosquito nets and mosquito-proof tents in the field are given.

Enteric fever.—The group is of all importance to the army. There appears to be a slight progressive decrease in the incidence and in the severity of the disease in British troops. In the Indian Army however in 1931 there was a rise both in the case mortality and in the incidence. In both armies, typhoid fever is the commonest type, followed by para A and B. There were 4 cases of 'C' type in the Indian troops. Eighty per cent of cases were diagnosed by blood culture, 25 per cent would have been diagnosed by faeces culture alone and 7.5 per cent by urine culture alone. Wilson and Blair's medium does not seem to give as good results in faeces culture as it does in sewage and water. An estimation of the 'O' and 'H' agglutinins has been carried out for some time. The results with the 'H' agglutinins are in consonance with work elsewhere

and the 'O' agglutinin results are not; but this pronouncement is not final as the 'O' emulsion may not have been satisfactory. The production of 'O' and 'H' agglutinins does not by any means run on parallel lines; this shows the value of carrying out tests for both types of agglutinins separately. The report concludes that 'as far as the diagnosis of these fevers is concerned, there is still no method or combination of methods which is infallible. The opinion of the discriminating physician must still remain the decisive factor in doubtful cases'.

Dengue and sandfly fever.—These are troublesome and cause much disability. In 1931, sandfly fever was the chief offender and caused 50 admissions per 1,000 of the whole army. In local areas such as Landi Kotal the figure was nearly 400 per 1,000. The prevention of sandfly fever must depend solely upon anti-larval methods, no other prophylactics, e.g., nets, etc., are of any use. (An investigation into the breeding habits of the sandfly at Landi Kotal, in which the Indian Research Fund Association is assisting, is at present being conducted.)

Pyrexia of uncertain origin.—This diagnosis is definitely allowed now in the army, and refers to cases where every effort has been made to give a definite diagnosis and has failed. An investigation into all such cases by dividing them into short (less than 7 days) and long (over 7 days) fevers did not yield much information, beyond the fact that certain of them were probably intestinal in origin.

Dysentery and diarrhoea.—These are troublesome factors and difficult of control. The reason is that these infections are, practically without exception, contracted in civil communities outside military control. About 12 per cent of the cases are returned as protozoal, 40 per cent definitely bacteriological and 48 per cent as clinical or having cellular exudates. The Flexner type largely predominates, agglutinating sera for types V, W, X, Y and Z are available but 22.5 per cent of isolated strains failed to agglutinate with these.

'Hoechst' polyvalent anti-dysenteric serum has given good curative results. On the whole the type of dysentery is mild.

Veneral diseases.—A 'disappointing' increase of 142 cases is recorded in 1931.

The usual preventive measures were carried out namely—

- (1) Propaganda and education.
- (2) Provision of games and amusements in barracks.
- (3) Prophylactic treatment rooms.
- (4) Preventive packets.

Smallpox.—Only 4 admissions in the British ranks occurred, with no deaths. Practically 100 per cent of all ranks are protected.

Ophthalmology.—An interesting investigation into trachoma in Sikh recruits showed that:—

(1) The disease is widespread amongst certain classes, particularly Sikhs, amongst whom well over 90 per cent are infected.

(2) Infection starts in childhood and in the great majority progresses to reach a quiescent stage which produces little disability.

(3) In the past, large numbers have been enlisted and served as efficient soldiers throughout their service.

(4) No evidence has been found to show that the disease is so infectious as to render the enlistment of these men a danger either to their fellows in the unit or to British troops serving with them.

In general hygiene, distinct progress goes on in housing, mosquito-proofing, dining halls, kitchen and bath houses. Hospital construction for Indian troops was materially advanced. At Lucknow, dissatisfaction with the municipal water supply has gone so far that it has been decided to provide a separate supply from deep wells for the cantonments.

Child welfare work, combined with maternity provision, continues to make good headway. This is an excellent feature of army hygiene.

The report on the Indian Army follows the same lines as that of the British troops, and most matters of interest common to both are included in the section on British troops.

The report also contains useful reference tables of statistical matter.

ABSTRACTED FROM THE ROCKEFELLER FOUNDATION: ANNUAL REPORT FOR THE YEAR 1932

Part I

GENERAL PUBLIC HEALTH PROGRAMME

THE present programme of the Rockefeller Foundation in public health calls for field research on problems in yellow fever, malaria, tuberculosis, and certain other diseases, with increasing emphasis on careful correlation of studies of disease in its environment with investigations in the laboratory. Through this procedure it becomes possible to define the problems with accuracy and to make headway in the search for more effective and less expensive methods of disease control.

A large amount of money is being spent throughout the world on applied public health, but a relatively small amount on research in connection with definite public health problems.

The Rockefeller Foundation is in a position to carry out research on disease in its natural environment, in almost any place in the world. Such research is always conducted in co-operation with government health departments. When the research is successful, the Foundation aims to assist the governments in preparing and trying out plans for the prevention of the so-called preventable diseases through the application of the knowledge gained by the research.

So long as public health research is limited to isolated stations in the field there will be bafflement from time to time because of the inability to carry promising lines of investigation to a conclusion such as can be arrived at only in a well-equipped base laboratory. The Rockefeller Foundation now has available such a laboratory at the Rockefeller Institute for Medical Research, which has placed adequate space at the disposal of the Foundation in one of its buildings. This laboratory, in which a successful method of vaccination against yellow fever has been devised and many other problems with regard to this disease have been cleared up, is now the backbone of all Foundation work against yellow fever. Work in this laboratory on research problems in other diseases, especially malaria, is under consideration.

YELLOW FEVER

Coming to grips with the disease in the laboratory has meant danger. In the first years of yellow fever work, after experimental animals became available, 33 cases of the disease with six deaths occurred among investigators, who had acquired the infection in the laboratory. A vaccine has now been developed which apparently has stopped all such infections.

High lights of the year were the continued success of vaccination against yellow fever; the verification in the State of Espirito Santo, Brazil, of a mild epidemic of yellow fever occurring in the absence of *Aedes aegypti*, the usual mosquito carrier; the clearing up of a moot point with regard to the virus in the mosquito host by findings tending to show that the virus does not multiply in the mosquito; and, finally, discoveries concerning the relationship between the complement fixation test and the protection test in yellow fever which will enable investigators to interpret the results of these tests with greater clarity.

In West Africa blood specimens were collected in Nigeria, Gold Coast, Dahomey, French Niger, French Sudan, Senegal, Sierra Leone, and Liberia for the purpose of ascertaining, by means of the protection test, whether the donors of these specimens had at any time had yellow fever. The sera of 4,368 natives

residing in 92 cities, towns, and villages were tested. These protection surveys, although incomplete, furnish important evidence on the distribution and epidemiology of yellow fever in Africa. In the regions studied no large area has completely escaped infection. It is clear that widespread unrecognized epidemics have existed in the recent past in many parts of the interior as well as in the coastal regions. It is also clear that reported cases are no index of the actual occurrence of the disease. But from the evidence it is concluded that there are relatively few places in Africa which may be classed as permanent endemic foci of yellow fever. The important reservoir of yellow fever in West Africa is composed principally of numerous epidemics which come and go in native towns.

It would be a mistake to consider the revelations of this immunity survey as indicating an extension of yellow fever and an increased danger. It is our understanding of the disease rather than the disease itself that is increasing. In general, at the present moment, outbreaks of yellow fever seem to be fewer than usual. A limited number of cases of the disease occurred in British territories in Africa during the year. In French territories the disease was more widespread. Thirty-nine cases, practically all of them in Europeans, with 36 deaths, were reported.

Studies of the virus.—In the Rockefeller Foundation laboratories studies of the yellow fever virus and methods of dealing with it are being continued. Viruses are distinguished from bacteria by their ability to pass through filters fine enough to retain the smallest ordinary bacteria and by their invisibility even under high magnification, although recent reports suggest that some of them have been made visible by a special technique. Moreover, viruses cannot be cultivated on ordinary non-living media. A large number of diseases of man, animals, and plants are now known to be due to infection by viruses.

In the yellow fever laboratory in New York the earliest specimens of yellow fever virus preserved by drying while in the frozen state are now over three years old, but they still retain the virus with no appreciable change in virulence. A new machine has been constructed for the automatic regulation of temperature and vacuum conditions during the drying of specimens. The temperature is kept at about -6°C .

Researches recently published show that the virus of yellow fever, as adapted to mice, has been maintained through more than one hundred passages in tissue culture without any change being induced in the property of the virus. It has again been demonstrated that living cells are necessary in the culture medium. The yellow fever virus is neutralized by immune serum in the presence of living cells. But once the virus has become intracellular it is able to withstand the action of concentrated immune serum, and in the cells it maintains a virulence corresponding to the virulence of normal cultures.

Experiments with yellow fever virus gave results which coincide with those obtained with smallpox virus. When the yellow fever virus was mixed simultaneously with monkey immune serum and fresh chicken embryonic tissue, after an incubation period of one to five days no virus was found in the fluid which had been separated from the cells by centrifugation, and very little virus was found in the cells. Only after a six-day cultivation period did definite virulence appear in the cellular part. Quite different results were obtained when the virus was allowed to act on the cells for one or two hours at room temperature before the immune serum was added. In that case the tissue cells, even in the presence of highly concentrated immune serum, retained the same virulence as in normal cultures. In the absence of living cells or on the addition of killed cells virulence is lost in a short time.

Another important study completed in 1932 dealt with the question as to whether yellow fever virus multiplies in the mosquito host. From analogy with malaria and other insect-borne diseases it was natural

to suppose that the disease-producing organism or virus is found in the mosquito because it needs the mosquito as a host in which to develop. This is true in malaria, where the cycle of development of the causal organism within the mosquito is well known. But it appears from the result of a series of delicate measuring experiments that in the highly effective insect host of yellow fever (*Aedes aegypti*) the quantity of virus present never surpasses that originally ingested. The mosquito, in biting the yellow fever patient, takes in, on the average, one million to two million lethal doses of yellow fever virus. This new study clears up an important point in the yellow fever infection cycle.

It was shown that although, exceptionally, the neurotropic yellow fever virus which produces encephalitis can be transferred by *Aedes aegypti*, the fixed neurotropic strain cannot be maintained in the mosquito host so well as the viscerotropic strain. This is probably due in part to the smaller amount of virus ingested by the mosquito on account of the paucity of the virus in the blood stream of the mammalian host.

Vaccination against yellow fever.—It is now possible to vaccinate small numbers of persons against yellow fever with reasonable safety. The virus used has almost completely lost its power to produce illness in monkeys. The immune serum prevents the circulation of the virus in the blood, and it is inconceivable that vaccinated persons might become a menace to their fellow men through the transfer of the altered virus by the mosquito. Although the disease is not produced in the vaccinated persons, a high degree of immunity develops in the course of two or three weeks.

Tests have been made which indicate that the preservation of yellow fever immune serum by rapid desiccation in a vacuum while frozen, and subsequent storage at refrigerator temperatures for a considerable period of time, cause no discernible reduction in the protective power of the serum.

The blood of 28 of the persons vaccinated in New York was tested for power to neutralize yellow fever virus in mice, and all gave this evidence of immunity. Fourteen of these persons were tested as long as one year after vaccination, and one was tested at the end of 18 months. In each case the serum was found to have definite protective power.

Although considerable research has failed to unearth any practical objection to the use of neurotropic virus in immunization against yellow fever if an adequate amount of immune serum is given also, it is obvious that the ideal vaccine virus would be one whose specific reactions had no relation to vital tissue. If a strain of yellow fever virus could be developed which would be incapable of producing harmful effects on any vital organ, this would be of importance in yellow fever control. With this in mind an attempt was made to adapt the neurotropic yellow fever virus to some tissue other than the brain or the tissues of the principal viscera. In the experiments conducted it was shown that the mouse-adapted neurotropic virus could live in the testicular tissues of mice but that the virus was not appreciably changed by a moderate number of passages in these tissues. These experiments have as yet offered no solution to the problem of finding a virus which is completely harmless. They point to the possibilities of further development of the work recounted above, which consists of growing neurotropic yellow fever virus in tissue cultures, entirely apart from living animals.

There are still distinct limitations to the application of the present method of vaccination. It cannot be used in a country into which the introduction of living virus would be dangerous or has been prohibited. In the second place it would be difficult to secure enough immune human serum from recovered or vaccinated persons to satisfy a large demand. A beginning has been made by vaccinating persons who desire protection against unusual exposure to yellow fever, especially those who are actively investigating the disease.

in the field or in the laboratory. Work is going forward in connection with the simplification of the process of vaccination. If simplification could be achieved the road would be open toward a more extensive use of this protective measure.

It seems probable that vaccination may be useful for the crews of aeroplanes making stops in infected regions and for certain travellers if they can thereby avoid quarantine restrictions placed on persons not immune to yellow fever.

Yellow fever without Aedes aegypti.—Although *Aedes aegypti* seems to be the only vector of yellow fever which ordinarily need be considered, several other mosquitoes have been shown in laboratory experiments to be capable of transmitting the infection by biting. Three additional species of *Aedes* in Brazil, and five additional species of *Aedes* in West Africa, as well as two other species of mosquito, have been incriminated.

It has been felt that the possibility of transmission of yellow fever in nature by the mosquitoes other than *Aedes aegypti* which have been incriminated as vectors in laboratory experiments should be kept in mind, particularly if the common stegomyia does not seem to be sufficiently numerous to account for the presence of the disease. During 1932 there was verified the actual occurrence of mild epidemic yellow fever in a region in which *Aedes aegypti* was not present. The only two mosquitoes on the suspicious list seen in the infected area were *Aedes (Ochlerotatus) scapularis* Rondani and *Aedes (Taeniorhynchus) fluviatilis*. *Aedes scapularis* was found more frequently and is believed to be the more dangerous species. The spontaneous disappearance of yellow fever in this area is attributed to the inefficiency of the insect vector rather than to failure of the human host.

It was found that the yellow fever virus may remain alive in ticks for considerable periods. But there was no indication that the virus was transmitted by the bites of infected ticks at any stage of life, nor was any evidence secured that yellow fever virus was passed from one generation of ticks to another through the egg, or that the virus persisted during the transformation of larva into nymph.

In the body of the bedbug (*Cimex hemipterus*) the virus of yellow fever appeared to die off so rapidly that the disease could not be transmitted by injection of the ground-up insects later than the second day after their infecting meal. It is possible that some active virus was eliminated in the faeces during the first and second days, but not later. In general, the bedbug was not incriminated as a vector of yellow fever.

Further experiments were made to determine whether yellow fever might be transmitted by dog fleas or biting stable flies. *Macacus rhesus* monkeys were used as the source of the virus. Experiments were of two kinds: interrupted feeding experiments in which the fleas and flies were allowed to bite an infected monkey and to finish their feeding on a normal monkey, and experiments in which fleas and flies, after having fed, were ground up and the ground mixture was injected intraperitoneally into a normal monkey.

Dog fleas did not transmit the virus of yellow fever in interrupted feeding experiments. The virus was not demonstrable in the bodies of the insects 18 hours after an infective blood meal. But fleas which had fed seven hours previously on an infected animal caused the death from yellow fever of a normal monkey into which they were injected. Stable flies transmitted yellow fever virus to a *rhesus* monkey in an interrupted feeding experiment six hours after an infective blood meal, but not 16 hours after such a meal. Flies which had fed as early as 42 hours previously on an infected monkey caused the death from yellow fever of a normal monkey into which they were injected. Thus the possibility that these two insects, the dog flea and the biting stable fly, might transmit yellow fever virus by interrupted feeding in nature is remote. The fact that the virus

dies out rapidly in the bodies of both insects decreases the probability of their being carriers of importance.

Studies of yellow fever in laboratory animals.—During 1932 there was undertaken an investigation of the specificity and accuracy of the immunity test now being widely used in epidemiological studies of yellow fever, namely, the intraperitoneal protection test in mice. Sera of persons in Canada and China who could never have been exposed to yellow fever virus were tested for protective power against this virus, and the results were compared with results of protection tests in countries where yellow fever is known to exist. The conclusion was that the test is highly specific and useful as an indicator of past infection.

During the year Dr. Max Theiler published another paper on the yellow fever protection test in mice by direct intracerebral injection. This method has certain advantages in that only small quantities of serum and virus are required. The possibility of using a simple intracerebral test in mice for determining quantitatively the amount of protective antibodies in yellow fever immune serum was investigated. Two methods of preparing the virus were used. In the first the virus was prepared fresh each time. There was found to be a great range in the amount of brain tissue containing one minimum lethal dose. The rate of deterioration of virus preparations, although these were made in accordance with a uniform technique, varied considerably. In the second method, preserved virus preparations were used. The limitations of the method of preserving the carefully standardized virus by drying it in the frozen state make the procedure unsuitable for use in the routine testing of sera by the method here presented. Before means are found for standardizing and preserving the virus in large amounts, it would be premature to advocate this method for the routine testing of yellow fever sera in epidemiological work.

The successful use of the mouse as a laboratory animal for yellow fever work led to the employment of the same technique with the guinea-pig. It was found that guinea-pigs are susceptible to intracerebral injections of yellow fever virus fixed for mice, but relatively insusceptible to intracerebral injections of yellow fever virus of monkey origin. The course of the disease produced in guinea-pigs is essentially the same as in mice, but the concentration of virus in the brain of the guinea-pig is much less. The blood plays no part in the distribution of the virus. At death, damage is confined to the nerve tissues. Continued passage of virus in the guinea-pig leads to no alteration in its disease-producing capacity for mice. It was shown also that intracerebral inoculation of neurotropic virus of mouse origin produces typical fatal encephalitis in the agouti, a small South American rodent (*Dasyprocta agouti*). However, the agouti is relatively resistant to the virus. The order of susceptibility in the case of these animals, namely, mouse, guinea-pig, and agouti, may be due in part to the fact that the virus used in the experiments had been adapted to the mouse.

The susceptibility of various Asiatic, African, and South American monkeys to intracerebral inoculation with mouse-brain-adapted yellow fever virus was also repeatedly demonstrated. It was shown that this neurotropic virus produces a well-marked encephalitis in monkeys, which runs a typical clinical course and causes characteristic lesions. Neurotropic yellow fever virus was transferred by intracerebral inoculation through three passages in *Callithrix* monkeys, with the production of uniformly fatal encephalitis. Intracerebral inoculation of another monkey, *Leontocebus ursulus*, with neurotropic yellow fever virus was followed by febrile reaction and in some instances by neurological symptoms and death. No success was obtained in an effort to transfer the virus in series to *L. ursulus*. It was found that encephalitis can exceptionally be caused in monkeys by the bites of stegomyia mosquitoes carrying neurotropic virus.

Aedes aegypti mosquitoes feed readily on certain species of bats. Attempts to transmit yellow fever virus to these bats by means of *Aedes aegypti* mosquitoes and later to obtain the virus from the bats were negative in result.

Complement fixation and precipitin tests.—Work done during the year has served to throw light on the reasons for the discrepancy between the results of the complement fixation test and those of the protection test. A precipitin test was evolved and found to be closely related to the complement fixation test. Positive results obtained from the complement fixation test or the precipitin test were found to be due not to the detection of the antibody which protects against the yellow fever virus itself, but to the presence of an entirely different anti-body (precipitin), produced in response to the presence of a protein substance (precipitinogen) resulting from cellular injury during the course of a severe attack of yellow fever. The precipitinogen disappears with recovery, and the corresponding antibody (precipitin) tends to disappear more rapidly than the protective antibodies resulting from the presence of living virus. In making the precipitin or complement fixation test, the antigen selected for use should be rich in precipitinogen.

The precipitin test promises to be of some value in the diagnosis of acute infections. By reversing the process, it is possible to test for precipitinogen during the acute disease, with a serum containing much precipitin. Since the test requires no extensive laboratory equipment, it is one that should be well adapted to field work.

(Note.—This report is always full of interest and on this occasion it is even fuller than usual. The result is that there is so much we wish to abstract that we have decided to divide it into two parts and publish the remainder in our next number.—Editor, I. M. G.).

ABSTRACT FROM THE ANNUAL REPORT FOR THE YEAR 1932 OF THE SOUTH AFRICAN INSTITUTE FOR MEDICAL RESEARCH, JOHANNESBURG. PUBLISHED BY THE SOUTH AFRICAN INSTITUTE FOR MEDICAL RESEARCH

DEPARTMENT OF BACTERIOLOGY

Pneumonia.—Investigations into the bacteriology and epidemiology of pneumonia as it occurs on the Witwatersrand have been continued throughout the year. A large number of specimens of morbid material from cases of pneumonia and allied acute respiratory diseases were bacteriologically examined. The finding previously reported that the streptococcus, *Staphylococcus aureus* and the *Bacillus influenzae* may be isolated from material in cases of pneumonia, along with or in the absence of the pneumococcus held true for the period under review. The importance of the multiplicity of organisms occurring in respiratory disease among the native labourers on the local mines lies in the fact that a pure pneumococcus vaccine as previously employed in prophylactic inoculation cannot be expected to exert a maximum immunizing effect under present conditions. The vaccine now used, therefore, contains the various prevalent strains of the pneumococcus together with representatives of the other organisms which have been isolated. Large-scale experiments have been, and are still being, conducted to test the value of this mixed vaccine. The evidence accumulated to date is becoming more and more convincing as to the efficacy of this prophylactic agent. On the mines where this means of prophylaxis is thoroughly carried out, a definite and significant diminution in the incidence and mortality rates is recorded, not only in pneumonia, but also in general respiratory infections. In the Northern Rhodesia copperfields, also, which the institute investigated from the point of view of pneumonia prophylaxis, a very satisfactory result has been obtained on one large mine which has adopted this

means of protection. Immediate scientific proof of the value of a particular method in pneumonia prophylaxis can, of course, not be obtained; to date, however, there can be but little question that the evidence in favour of vaccine prophylaxis is more than favourable when inoculated and non-inoculated mining communities are compared.

A striking witness to the efficacy of the immunizing action of the various pneumococci present in the vaccine is the finding that from cases of pneumonia in non-vaccinated persons the old-time virulent pneumococci are frequently isolated, whereas from material in pneumonia occurring in those who have been vaccinated the vaccine strains of this organism are but rarely found. In the latter case various unclassified pneumococci and other organisms are obtained on cultivation of specimens.

Complement in human blood.—A beginning was made in the quantitative study of the blood complement in man and also from the point of view of the part played by it in immunity reactions.

Large numbers of blood specimens were examined from healthy persons, European and native, and from patients suffering from various diseases. These diseases included pneumonia, enteric fever, multiple abscesses, leprosy, allergic conditions, skin diseases and cancer.

A large number of natives suffering from pulmonary tuberculosis was examined. These men were all about to be repatriated to their homes on account of the disease, and in this group a considerable proportion of the patients showed either very slight amounts or no complement in the blood. In these cases the clinical prognosis was almost invariably bad. In nearly 100 leprosy cases examined a similar parallelism was noticed between low complement content and bad prognosis. In cancer cases no such parallelism was observed.

Rabies.—An investigation of South African strains of rabies virus was begun. Nearly every investigated case of human rabies in this country has been found to have been caused by the bite of the yellow mongoose or genet cat. A few cases of rabies have been ascribed to the bite of a dog, but in view of the comparatively wide contact of dogs and meercats in the rural districts, it is surprising that rabies in dogs is of such comparatively rare occurrence, and on this account and from the point of view that in nature the disease is confined to carnivores, the possibility is suggested of South African rabies being a modified form of true rabies. A number of strains of true rabies virus were imported from India for comparison with South African strains by means of cross protection and other tests. The overseas strains, however, have not been found viable on arrival in South Africa and further efforts are being made to obtain a living strain of the Indian virus.

Service Notes

APPOINTMENTS AND TRANSFERS

THE services of Col. A. H. Proctor, D.S.O., V.H.S., officiating Surgeon-General with the Government of Bengal, were placed at the disposal of the Government of India with effect from the 1st December, 1933, on which date he was relieved of his appointment under this Government.

Col. A. H. Proctor, D.S.O., V.H.S., is appointed Inspector-General of Civil Hospitals, United Provinces, with effect from the 9th December, 1933.

Lieut.-Col. H. C. Buckley is appointed Inspector-General of Civil Hospitals, Bihar and Orissa, with effect from the afternoon of the 16th December, 1933.

Lieut.-Col. N. M. Wilson, O.B.E., Chief Medical Officer, Delhi, is appointed Inspector-General of Civil Hospitals, Central Provinces, with effect from the 2nd January, 1934.

The services of Lieut.-Col. R. C. Clifford, M.C., D.S.O., are placed permanently at the disposal of the Government of the United Provinces, with effect from the afternoon of the 30th June, 1930.

Lieut.-Col. K. G. Gharpurey, Civil Surgeon, Belgaum, is appointed to officiate as Surgeon-General with the Government of Bombay during the absence on leave of Major-General H. R. Nutt, V.H.S.

The services of Major A. J. D'Souza, M.C., are placed at the disposal of the Government of Burma for employment in the Burma Jail Department with effect from the date on which he assumes charge of his duties.

Captain J. C. Drummond, whose services have been replaced temporarily at the disposal of the Government of Bengal, is posted at the Medical College Hospitals, Calcutta, until further orders.

This cancels previous notification.

LEAVE

Major-General H. R. Nutt, V.H.S., Surgeon-General with the Government of Bombay, is granted leave on average pay for 7 months and 27 days, with effect from the 29th January, 1934, or subsequent date from which he may avail himself of it.

Major J. S. Galvin, Civil Surgeon, Sholapur, is granted leave on average pay for 8 months, with effect from the 6th April, 1934, or subsequent date of availing.

PROMOTIONS

Colonel to be Major-General

Sir Frank Powell Connor, Kt., D.S.O., V.H.S. Dated 15th November, 1933.

Lieut.-Col. to be Colonel

I. M. Macrae, C.I.E., O.B.E. Dated 15th November, 1933, with seniority 1st March, 1928.

Note.—The promotion of Major N. S. Jatar, D.S.O., to the rank of Major is ante-dated to 1st February, 1926.

To be Brevet-Major

Capt. F. M. Collins. Dated 1st January, 1934.

RELINQUISHMENT OF APPOINTMENTS

The undermentioned officers relinquish their probationary appointments:—

20th December, 1933.

Lieut. (on prob.) F. I. Ashton.

Lieut. (on prob.) J. F. J. Doyle.

RETIREMENTS

Major-General Sir John W. D. Megaw, K.C.I.E., K.H.P. 15th November, 1933.

Col. F. E. Wilson. 7th November, 1933.

Lieut.-Col. M. S. Irani. Dated 17th November, 1933.

Notes

B. W. & CO'S PROCAINE AND ADRENALINE PRODUCTS

BURROUGHS WELLCOME & Co. have introduced three procaine and adrenaline products for use as local anæsthetics.

'Hypoloid' procaine and adrenaline presents procaine hydrochloride 0.02 gm. and adrenaline 0.0001 gm. in 1 c.cm. in solution ready for immediate use. Issued in boxes of ten 'Hypoloid' ampoules.

Each 'Tabloid' hypodermic procaine and adrenaline contains procaine hydrochloride 0.02 gm., adrenaline 0.0001 gm. and sodium chloride 0.009 gm., and a solution can be readily made in the barrel of a syringe. Procaine hydrochloride is often considered far superior to a general anæsthetic for the reduction of fractures, for which purpose the 'Tabloid' product containing sodium chloride should prove valuable. Issued in tubes of twenty.

'Wellcome' brand procaine dental anæsthetic solution is available in bottles of 25 c.cm. Each c.cm. contains procaine hydrochloride 0.02 gm. and adrenaline 0.0001 gm.

RESULTS OF GOLD THERAPY

STATISTICALLY the results of gold therapy are difficult to present; but it has been observed from experience of hundreds of lung and laryngeal cases during the last seventeen years, that gold is capable of promoting the cicatrization of the foel, and the healing processes thereby. Especially clearly was this seen in laryngeal tuberculosis.

RESULTS IN 1,289 CASES OF LARYNGEAL TUBERCULOSIS FROM THE YEARS 1907 TO 1931

	No.	Cured	Better	No change	Worse
Without gold therapy.	962	358 =37.2%	201 =20.9%	210 =21.8%	193 =20.1%
With gold therapy.	327	167 =51.1%	115 =35.2%	18 =5.5%	27 =8.2%

The intramuscular injection of gold oils appears to improve the results still more, because by this method of administration it is possible to store in the body larger quantities of gold, and in a sense to bring about a continuous action.

Technique.—Watery solutions of gold salts are as a rule given intravenously. Smaller doses with longer intervals (initial dose 1 mg., final dose according to the tolerance, 0.1 to 0.25 g.; an injection every eight to ten days) are preferred. In the intramuscular administration of gold oil (oleosolganal, solganal oleosum, Sehering) an advance is registered. From experience, it is best to give injections twice a week, rising from 0.005 to 1.0 of the preparation. Some kidney disturbances were seen, but they were usually limited to a mild form of nephropathia aurea. The other toxic manifestations were less frequent and less severe. These gold oils are therefore to be preferred to all other gold preparations.

COLLOSOL BRAND HALIBUT-LIVER OIL

THE Crookes Laboratories were amongst the first to introduce halibut-liver oil to the medical profession of the United Kingdom. It is claimed that Collosol brand halibut-liver oil represents the finest quality halibut-liver oil on the market. The secret is due to the special solvent-free extraction process, evolved in and employed by the Crookes Laboratories, which enables a beautiful, pure, golden oil to be presented with a vitamin-A value of at least 80 times and a vitamin-D value at least 10 times that of the very finest cod-liver oil.

The great attention to detail which is associated with all the products emanating from the Crookes Laboratories is evinced by a label which is affixed to each bottle of Collosol brand halibut-liver oil stating the number of the particular batch, the date of bottling and the vitamin value by the antimony trichloride test, the biological test and the spectroscopic test.

The range includes the oil, capsules, Halimalt (Collosol Brand Halibut Oil and Malt Extract) and Halidexol (an extremely palatable halibut-liver oil emulsion).

PANDIGAL AND THE GLUCOSIDES OF DIGITALIS LANATA

AMONG the pharmacopœial drugs digitalis occupies a position of such importance that there has been no want of study directed towards the isolation of the active principles.

The reason why this question has become so important is determined by the fact that the drug contains a

number of glucosides whose pharmacological action varies with the locality and the harvesting of the plant. The biological assay of two samples of *folia digitalis* or of two extracts of the leaves may agree in all points within the limit of errors.

Yet the relationship between the several glucosides can vary, so that there is a difference in their therapeutic effects. So far, the vast amount of research work devoted to the isolation of uniform glucosides from *Digitalis purpurea* which might be utilized in a pure state for therapeutic purposes has not led to any definite result.

Moreover, the production of pure purpurea-glucoside is fraught with such difficulties that the only one sold in a pure state is digitoxin; owing to its cumulative effect, however, it has found little favour in therapeutics.

Working on *Digitalis lanata* which is extensively cultivated in Austria, Mannich, Mauss, and Mohs succeeded in isolating four hitherto unknown glucosides among which lanata-glucoside I or, as they termed it, lanadigin is of particular interest.

It was also proved that solutions of lanadigin can be kept for 12 years without suffering even a slight loss of potency. A great advantage rests in the fact that it can be sterilized.

Lanadigin is a uniform and chemically-pure body, therefore invariable in action and the standardizing of its potency by biological assay becomes wholly unnecessary.

The new preparation Pandigal contains this glucoside.

MALNUTRITION AMONG CHILDREN AND ADULTS

A New York newspaper has recently published an article which reveals the alarming proportions to which malnutrition among school children has grown as a result of the economic crisis. It is stated that malnutrition among school children has increased 56 per cent in the last six years, endangering the health of millions of children. This danger threatens especially the poorer classes because their diet is, as a general rule, not so well balanced. By careful tests he found that the breakfasts consumed by many children did not contain more than about half the amount of calories required, according to scientific standards, and even their lunches were deficient in this respect.

The question of supplying nutritious, well-balanced food at low cost is a most important one while the world crisis lasts. Doctors and diet experts have been calling attention to the advantages which certain cereal foods offer because of their exceptional nourishing properties and low cost. Of all the cereals, oats, and especially Quaker Oats, stands out on account of its exceptionally high protein contents, which is much greater than that of wheat or rice, two of the most commonly used cereals.

Many timid, nervous children are often the victims of unbalanced foods. If their food does not give them the minerals which they require for their nerves, the vitamins for their growth and the carbohydrates which give them energy, it is quite certain that they do not have a balanced diet. Quaker Oats contain the right proportions of vital elements to build the nerves and other tissues of the body.

Although the results of malnutrition in adults may be very serious, they may be even worse in children, because it retards their growth and lowers the natural resistance which they need so much to combat the many illnesses which constantly beset them.

TANNIC ACID OUTFIT FOR BURNS

THE tannic acid treatment of burns by means of a spray has been recommended for several years, but the importance of using a freshly-made solution of tannic acid has prevented its universal adoption.

Packets of the powder for this purpose were bulky and inconvenient, but the introduction of compressed tablets, as suggested in the *British Medical Journal* of

18th March, 1933, has eliminated this difficulty, and it is now possible to produce the required solution in a few minutes with the minimum of trouble. The

tablets, which also contain a small proportion of perchloride of mercury and boric acid, are of such strength that one tablet dissolved in 2 ounces of warm water produces a 2 per cent solution of tannic acid. This forms an admirable first-aid dressing, easily applied by means of a spray or on linen or layers of sterile gauze thoroughly soaked in the solution.

A tannic acid outfit for burns comprising an amber bottle with vulcanite spray and best red rubber bellows, together with a supply of tablets, complete in cardboard box as illustrated above is put on the market by C. J. Hewlett and Son, Ltd., 35-42, Charlotte Street, London, E. C. 2, and sold at 5 shillings.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

MEGACOLON AND ITS TREATMENT BY SYMPATHECTOMY*

By D. C. CHAKRABARTI, F.R.C.S. (Edin.)

Surgeon, Campbell Hospital, Calcutta

MEGACOLON is defined as dilatation and hypertrophy of a part or of the whole colon without any palpable obstructive lesion in it. It has been divided into two classes, *viz*, congenital and acquired.

In the majority of cases the sigmoid colon is the part affected, but the dilatation may extend in a few cases through the whole length of the large intestine. This condition is accompanied by dilatation of the bladder in a very small number of cases.

Theories.—Three main theories have been put forward to account for its aetiology, *viz*, (a) developmental, (b) mechanical and (c) neurogenic.

(a) *The developmental theory.*—Some say that it is a developmental dilatation with secondary hypertrophy, others that it is a developmental hypertrophy with secondary dilatation, and according to Hirschsprung it is a combined dilatation and hypertrophy of developmental origin. But no one has explained the developmental error.

(b) *The mechanical theory.*—The following have been held as responsible for this condition—kinking at the pelvi-rectal junction, valves, rectal and anal atresia, etc., but the dilatation of the bladder accompanying it in a small number of cases cannot be explained by any mechanical change in the colon.

(c) *The neurogenic theory.*—Reflex spasm of internal sphincter, non-relaxation of the sphincter, and paralysis of a segment of the bowel have been mentioned as possible causes of this condition. These may be due to relative over-activity of the sympathetic. The circular fibres of the sigmoid colon are supplied by a definite branch of the hypogastric or presacral nerve. This has been confirmed by Learmonth. Relief obtained after resection of this nerve and occasional association of a dilated bladder are points in favour of this theory. The operative treatment is entirely based on this theory.

Some knowledge of the anatomy of this nerve is necessary in order to enable the reader to follow the different steps of the operation.

Anatomy of the hypogastric nerve.—It is not a single nerve but a plexus of nerves running vertically downwards from below the bifurcation of the aorta. It has three roots—one middle

and two lateral. The middle root is the continuation of the aortic plexus. The two lateral roots arise from the ganglia of the lumbar sympathetic and passing medially to the lower extremity of the aortic plexus take part in the formation of the hypogastric nerve at the level of the bifurcation of the aorta. This nerve enters the pelvis and divides into two branches each ending in the hypogastric ganglion situated on the lateral wall of the rectum. Sympathetic nerves for the sigmoid colon leave the aortic plexus above the origin of the hypogastric nerve and pass outwards to be distributed along with the branches of the inferior mesenteric artery.

The parasympathetic nerve supply of the pelvic viscera arises from the second, third and fourth sacral nerves. They form the nervus erigens or pelvic nerve. This also passes through the hypogastric ganglion and its branches are distributed to the wall of the pelvic viscera.

Physiology.—Stimulation of the sympathetic nerves causes contraction of the sphincters of rectum and bladder and dilatation of the walls of these viscera. Stimulation of the parasympathetic produces the opposite effect. In health these two sets of nerves are in a state of physiological balance. If this balance is upset in any way it will lead to over-action of one set of fibres. So megacolon is supposed to be due to relative over-activity of the sympathetic.

The idea of the operation, *i.e.*, resection of the hypogastric nerve described afterwards, is that if the sympathetic nerve supply is cut off the parasympathetic will have its unrestricted action and will cause relaxation of the sphincters and contraction of the bowel wall.

The neurogenic theory is supported by the following case:—

A Mahomedan male, aged about 45, tailor by occupation, was admitted into the medical wards of the Campbell Hospital on the 2nd April, 1933, and transferred to the writer's ward on the 26th April.

Chief complaints

(a) Obstinate constipation, bowels would not move even once in a fortnight. Even four ounces of castor oil made the bowels move only once and that not satisfactorily.

(b) Distension of the abdomen. Before operation the measurements of the abdomen were 51½ inches at a point midway between the xiphoid process and the umbilicus, and 55 inches at the level of the umbilicus.

(c) Loss of appetite.

(d) Pain in the right shoulder joint.

Duration.—About five years.

Skiaogram no. 1 was taken in November 1932 when the patient was in the medical wards for the same complaint. It shows extreme dilatation of the whole colon. No obstruction or kinking is noticed. Eight pints of barium enema had to be introduced and even then the shadow of the colon was not distinct in places. Sacculations of the colon are conspicuous by their absence.

Rectal examination—nothing abnormal noted.

In the absence of any obstructive lesion this case was thought to be neurogenic in origin and sympathectomy was decided upon.

* Being a paper read at a clinical meeting of the Calcutta branch of the British Medical Association on 20th October, 1933.

Operation (Cotte's operation)

A left paramedian incision about 6 inches long was made in the anterior abdominal wall from the level of the umbilicus downward. The rectus sheath was opened and the muscle was

Skiagram no. 1.
(Before operation.)

retracted laterally. The peritoneum was opened and the whole colon was found to be hypertrophied and dilated to a considerable degree. It was of the size of a balloon rubber tyre. The patient was then placed in the Trendelenburg position. The coils of the small intestine were packed off to the right side and the distended sigmoid colon had to be brought out. No kinking or obstructive lesion could be elicited. The promontory, the bifurcation of the aorta and the inferior mesenteric artery were identified. The posterior parietal peritoneum was incised vertically from below the bifurcation of the aorta, and a thick layer of fat was found there. With great difficulty the nerve plexuses were identified in this fatty tissue. The hypogastric nerve was cut transversely below, the cut end was held by a pair of artery forceps and drawn over to the patient's left side, and the roots from the right lumbar ganglia were divided. The aortic plexus forming the middle

root of the nerve was divided transversely above. The left root which generally forms a ring round the origin of the inferior mesenteric artery was divided and about an inch of the artery was denuded of everything. The nerve accompanying the artery and supplying the sigmoid colon was also divided. The hypogastric nerve being then free could be removed easily. The opening in the posterior parietal peritoneum was closed, and intestines were placed back in position, and the anterior abdominal wall was closed layer by layer.

Results of the operation

(1) The bowels started moving regularly from the ninth day of the operation.
(2) The patient complained of frequency of micturition from the fifth or sixth day of the operation.

(3) The distension of the abdomen gradually became less and less and the abdomen assumed normal size.

At the time of discharge measurements were 33 and 35 inches, respectively, at a point midway between the umbilicus and the xiphoid process and at the level of the umbilicus.

Skiagram no. 2.
(One month after operation)

(4) One ounce of castor oil was sufficient to move the bowels three or four times.

(5) Appetite—improved considerably.

(6) Pain in the right shoulder gradually disappeared.

In fact the patient appeared to be quite normal at the time of discharge.

Skiagram no. 2 was taken about a month after the operation and it shows marked changes in the size of the sigmoid and transverse colon. The haustra were quite distinct in these two parts of the colon.

Skiagram no. 3 was taken three months after the operation and showed further improvement.

Skiagram no. 3.
(Three months after operation)

Three pints of barium enema were sufficient to fill up the whole colon.

During his three months' stay in the hospital after the operation the bowels did not cause any serious trouble, the general health improved and he gained in weight. The complaint of frequency of micturition persisted to a certain extent, till his discharge.

The writer is indebted to Adamson and Aird's (1932) article on megacolon for the description of this condition.

ACUTE PERFORATION AND HÆMATEMESIS IN DUODENAL ULCER

By P. N. RAY, B.A., M.B., F.R.C.S. (Eng.)

Hon'y. Junior Visiting Surgeon, Medical College Hospitals, Calcutta

Perforation

ACUTE perforation is a grave complication of duodenal ulcer and its surgical treatment is one of the greatest urgency. The following case has so many unusual features that it seems worthy of record:—

Mrs. K. B., aged 16, was admitted under my care with an 'acute abdomen'.

History of present illness.—Just over two days ago, the patient complained of a sudden attack of severe pain over the pit of the stomach. During the next few hours, there was some relief of pain, but gradually it became generalized and most of it was felt over the lower abdomen. Collapse was complete by the time the patient was brought down to Calcutta for treatment.

History of past illness.—About eight years ago, she had an attack of cholera. There was no previous history of indigestion, but the patient suffered from habitual constipation.

Condition on admission.—Temperature—99°F.; pulse—150, and respiration—30 per minute. The radial pulse was just palpable.

On examination.—Tongue—dry and coated; cheeks—sunken; abdomen—marked distension. No local tenderness or rigidity was present. Liver dullness was obliterated, but shifting dullness was present. On vaginal examination, fluid was detected in the pouch of Douglas and there was a scanty blood discharge from the vagina.

Menstrual history.—Last period 10 days ago; no period was missed. The patient was married one year ago, but there was no issue. Her menstrual periods were rather irregular, but the discharges were normal.

Operation.—(Anæsthesia: open ether and chloroform.) One ounce of saline with glucose was administered intravenously during the operation.

A right paramedian incision was made opposite the umbilicus. The peritoneal cavity was full of cloudy sero-purulent fluid but without any odour. No pelvic abnormality was discovered, and the appendix was found normal. On enlarging the incision upwards, well-marked fat necrosis of the omentum was instantly noticed. A perforation was discovered in the first part of the duodenum, admitting the tip of the little finger. It was closed by means of Lembert sutures and over it an omental graft was apposed. The right paracolic gutter and the pelvic cavity were full of fluid; this was carefully mopped out. Rutherford Morison's pouch was drained in the usual manner and a suprapubic drainage was left in.

The patient passed through a very stormy post-operative period, but she recovered.

Commentary

Owing to the presence of a vaginal discharge containing blood and the complete absence of any previous history of indigestion, the possibility of a ruptured ectopic gestation could not be ruled out. The presence of shifting dullness, associated with absence of liver dullness, and the history of an acute onset with severe epigastric pain were points in favour of perforation of a peptic ulcer. But on these grounds it was not possible to exclude perforative appendicitis. The diagnosis was confirmed by making a rapid exploration of the pelvic cavity and the right iliac fossa.

The perforation of a duodenal ulcer in so young a subject as a girl of 16 is certainly very unusual in Calcutta. In hospital practice, the incidence of duodenal ulcer in the young female appears to be comparatively uncommon in this country. According to Wilkie (1933), duodenal ulcer is more than twice as common as gastric ulcer in the female. The patient was brought to the hospital more than 40 hours, after the perforation, with generalized peritonitis. It is of much interest to note that well-marked fat necrosis was present. Two other instances have been mentioned by Sherren (Choyce, 1932). Recovery in a case like this is exceptional, because the result of operations after 48 hours of acute perforation is almost invariably fatal (McCreery, 1924). The cause of the vaginal discharge in this patient is not clear. It might have been due to an irregular menstrual flow produced by the shock or more probably it was the result of pelvic peritonitis.

The ætiology of duodenal ulcer has not been cleared up. None of the theories of causation is wholly adequate. The important predisposing causes are irregular meals, unhygienic surroundings, excessive smoking and lack of sleep. Cushing (1932) has drawn attention to the fact that nervous instability of the vagotonic type, associated with continued mental worry and anxiety, and heavy responsibility, is prone to produce a hyperactive and hypersecretory stomach. In the young, acute ulceration with early perforation is not uncommon, but in the case of chronic ulcer in a patient aged 35 or more, usually there is a history of dyspepsia for years. It is known that, normally, the duodenal contents are regurgitated into the stomach from time to time by the contraction of the duodenal bulb in the presence of the relaxation of the pyloric sphincter. Undoubtedly, the duodenal reflux is an important mechanism for the regulation of gastric acidity. When it fails, gastric acidity is apt to rise and the neutralization of the highly-acid gastric contents takes place in the duodenum. This fact has been regarded as an important predisposing factor for the development of duodenal ulcer. Once the ulcer has developed, the healing process is retarded by the devitalizing action of the highly-acid gastric contents. Recently, convincing evidence has been adduced in support of the occurrence of ulceration in spite of pyloric relaxation and duodenal reflex, especially in case of jejunal ulcer after gastrojejunostomy (Fontaine and Kunlin, 1932). In this connection, it is of interest to note that, although rare, instances of perforation of duodenal ulcer after gastrojejunostomy have been recorded.

My reason for referring briefly to these points is to emphasize the rationale of surgical treatment in cases of duodenal perforation. In this country, the rate of mortality is high, because the patient seldom comes to the hospital before the onset of generalized peritonitis. Recent statistics show that the percentage of mortality

of duodenal perforation is 12.22, but within 12 hours it is only 8.82 per cent (Seotson, 1933). With regard to the type of operation, it is reasonable to perform the one which will give the immediate lowest mortality. Fortunately in most cases it is possible to close the perforation by inversion and suture. The ultimate result may also be claimed as satisfactory because two-thirds of the patients remained permanently free of gastric complaints (White and Patterson, 1931). It is however essential that a strict regulation of diet with exclusion of all spicy and indigestible articles of food and restriction of smoking are enforced for at least six months after the operation. Further, for at least two years after the subsidence of all symptoms in such a patient, there should be a revision of the case by his medical adviser at regular intervals.

Hæmatemesis

Acute hæmatemesis may be a most alarming complication of duodenal ulcer and it may be of such severity as to terminate fatally. Hæmatemesis occurs in about 30 per cent of cases of gastric and duodenal ulcers. The following case is of interest, on account of its severity and successful treatment:

S., Bengali male, aged 32, was admitted into the Prince of Wales Hospital, complaining of indigestion and abdominal pain of several years' duration; occupation—clerk in a jute mill.

History of present illness.—The patient gave a typical history of duodenal ulcer of several years' duration. The attacks of abdominal pain recurred with a definite periodicity, but, for the last six months, the character of the pain was completely changed. The pain began almost immediately after the intake of food. Though not severe, the pain was almost constant in the epigastrium and was dull aching in character. He did not seek surgical advice earlier because he regarded his condition as 'chronic dyspepsia' and because it did not interfere with his occupation.

History of past illness.—Recurrent attacks of malaria.

On examination.—General health—poor; tongue—coated; teeth—pyorrhœa alveolaris present.

On abdominal examination, no definite signs could be elicited except tenderness in the epigastrium and the right iliac fossa.

On skiagraphy (barium meal).—The stomach tone was poor and it was somewhat dilated. There was well-marked irregularity of the duodenal cap. There was a distinct niche in the lesser curvature close to the pylorus. After six hours, there was a residue in the stomach.

Onset of hæmatemesis.—On the day after the barium meal, the patient had a sudden attack of hæmatemesis. The vomited material amounted to nearly 16 ounces. The usual medical treatment was promptly instituted. Twenty-four hours later, he had a more severe attack, bringing out nearly a pint of blood mixed with clots. The collapse was complete and he passed a very precarious night. Next day, a suitable donor was found and eight ounces of blood was transfused with immediate benefit. There was no further hæmatemesis, but melæna continued for the next three days. A week later, another transfusion of eight ounces of blood was carried out. On both these occasions, it has to be recorded that several students in our ward volunteered for the transfusion, and two of them were selected after blood grouping.

Commentary

Hæmatemesis is usually a late complication of duodenal ulcer. It is in the nature of a secondary hæmorrhage, and clinically it appears either in recurrent small quantities or in a sudden massive flow. Sometimes one follows the other. In the first type, the ulcer is active and has a spreading margin and possibly produces satellite ulcers. In the second type, a large vessel is eroded, e.g., the gastroduodenal, the splenic and rarely other arteries. The severe hæmorrhage is usually preceded by exacerbation of gastric symptoms and also by one or two apparently trivial attacks of bleeding. Recovery is not common after massive hæmorrhage from a large artery. Fortunately, this patient recovered after passing through a very anxious time. It is difficult to say if the barium meal had anything to do with the onset of hæmatemesis. There is no doubt that after his admission into the hospital, there was complete relief of abdominal pain, as a result of strict regulation of diet.

With regard to treatment, the general consensus of opinion is that it resolves into two parts, (i) immediate life-saving measures and (ii) treatment of the ulcer.

The former consists of prompt medical treatment. As a general rule, operative measures are postponed till the patient has sufficiently recovered to withstand them. Occasionally, the hæmatemesis may be severe and lead to death so rapidly that there is no time for surgical treatment. Unfortunately, hæmorrhage may continue in some patients even after the operation. Mere ligation of the vessel is not enough, as bleeding is liable to recur. Usually the general condition of the patient is so low, that a serious operation is not justified and the rate of immediate mortality is unduly high. The mortality after medical treatment alone is about 3.8 per cent, but after surgical treatment the rate of mortality is considerably increased (Ogilvie, 1929). There is no doubt that, in general, medical treatment should be carried out for the arrest of hæmorrhage. Two or three weeks later, when the general condition of the patient has sufficiently improved, surgical treatment may be successfully undertaken. Infolding of the ulcer is a method that can be adopted in an emergency. The more reliable methods are excision or destruction of the ulcer by cautery, but in most cases gastrojejunostomy should be performed. The immediate results of treatment are better in duodenal than in gastric ulcer; the remote are not so favourable (Sherren, 1925).

Summary

(1) A case of perforation of duodenal ulcer in a girl of 16 has been described, in whom perforation was the first symptom of ulceration.

(2) The patient made a remarkable recovery, although she was operated upon more than 48

VOELCKER'S METHOD OF EXTRAPERITONEALIZATION OF THE URINARY BLADDER: ITS USEFULNESS IN OPERATIONS FOR PATHOLOGICAL CONDITIONS OF THE BLADDER AND THE URETERS

By V. M. KAIKINI, B.A., M.B., B.S., F.R.C.S. (Edin.)
Honorary Surgeon, King Edward Memorial Hospital,
Bombay

THE peritoneum is very loosely fastened to the anterior and posterior walls of the bladder but it is firmly attached to the vertex of the bladder over an area about an inch in diameter, and this prevents the complete freeing of the bladder.

When the bladder is filled with air or fluid, because of the loose attachment of the peritoneum to the anterior bladder wall, it is possible to expose a large part of this by pushing the peritoneum upward by blunt dissection. But in dealing with pathological conditions, such as tumours, of the vertex or the posterior and lateral walls of the bladder, where greater accessibility and exposure are necessary, this amount of extraperitoneal exposure of the bladder will not suffice.

In Rydygier's method the bladder is opened by an incision through the peritoneal cavity,

(Continued from previous column)

hours after the perforation. It is of interest to note that there was well-marked fat necrosis of the omentum.

(3) An unusual case of hæmatemesis, complicating a duodenal ulcer, has been described. The onset was not preceded by any of the usual warning signals.

(4) The efficacy of medical treatment, combined with repeated transfusion of blood, is clearly demonstrated in this case.

In conclusion, I wish to thank my house-surgeons, Dr. R. Roy and Dr. M. Chakravarti, for their valuable assistance.

The ultimate result may also be claimed as satisfactory because two-thirds of the patients remained permanently free of gastric complaints (White and Patterson, 1931). It is however essential that a strict regulation of diet with exclusion of all spicy and indigestible articles of food and restriction of smoking are enforced for at least six months after the operation. Further, for at least two years after the subsidence of all symptoms in such a patient, there should be a revision of the case by his medical adviser at regular intervals.

Hæmatemesis

Acute hæmatemesis may be a most alarming complication of duodenal ulcer and it may be of such severity as to terminate fatally. Hæmatemesis occurs in about 30 per cent of cases of gastric and duodenal ulcers. The following case is of interest, on account of its severity and successful treatment :

S., Bengali male, aged 32, was admitted into the Prince of Wales Hospital, complaining of indigestion and abdominal pain of several years' duration; occupation—clerk in a jute mill.

History of present illness.—The patient gave a typical history of duodenal ulcer of several years' duration. The attacks of abdominal pain recurred with a definite periodicity, but, for the last six months, the character of the pain was completely changed. The pain began almost immediately after the intake of food. Though not severe, the pain was almost constant in the epigastrium and was dull aching in character. He did not seek surgical advice earlier because he regarded his condition as 'chronic dyspepsia' and because it did not interfere with his occupation.

History of past illness.—Recurrent attacks of malaria.

On examination.—General health—poor; tongue—coated; teeth—pyorrhœa alveolaris present.

On abdominal examination, no definite signs could be elicited except tenderness in the epigastrium and the right iliac fossa.

On skiagraphy (barium meal).—The stomach tone was poor and it was somewhat dilated. There was well-marked irregularity of the duodenal cap. There was a distinct niche in the lesser curvature close to the pylorus. After six hours, there was a residue in the stomach.

Onset of hæmatemesis.—On the day after the barium meal, the patient had a sudden attack of hæmatemesis. The vomited material amounted to nearly 16 ounces. The usual medical treatment was promptly instituted. Twenty-four hours later, he had a more severe attack, bringing out nearly a pint of blood mixed with clots. The collapse was complete and he passed a very precarious night. Next day, a suitable donor was found and eight ounces of blood was transfused with immediate benefit. There was no further hæmatemesis, but melæna continued for the next three days. A week later, another transfusion of eight ounces of blood was carried out. On both these occasions, it has to be recorded that several students in our ward volunteered for the transfusion, and two of them were selected after blood grouping.

The bladder is now completely free and detached from the peritoneal cavity, so that it can be opened freely for any operative measures without any risk of contamination of the peritoneal cavity (figure 3).

The principal advantages of the Voelcker method are:—(a) Superior accessibility to the bladder, without any risk of contamination of the peritoneal cavity. (b) The change in the normal anatomical relationship between the peritoneum and bladder created by this procedure is only temporary, as it is found that in a short time the normal relationship establishes itself.

Two operations where this method was used are here reported; one was the removal of a portion of the trigone of the bladder for malignant papilloma, and the other the removal of stones in the bladder and ureter at one sitting.

Case 1.—Diagnosis—malignant papilloma.

V. B., male, aged 30, admitted for painless hæmaturia for the last ten months. On cystoscopic examination a sessile papillomatous growth was found very close to the right ureter (figure 4).

Fig. 4.—Cystoscopic appearance of the trigone of the bladder showing the papilloma and the opening of the right ureter.

The abdomen was opened through a vertical incision. Instead of extraperitonealizing the bladder according to Voelcker's method an attempt was made to detach the peritoneum from the bladder wall according to Lichtenberg's method. This attempt caused ugly tears in the bladder wall, which was already thinned out on account of the bladder being distended with fluid at the beginning of the operation. The peritoneum was thus detached with small portions of the bladder muscle attached to it. The tears in the bladder were at once closed to prevent contamination of the peritoneal cavity and the peritoneal cavity was deliberately opened, to carry out the steps as described in Voelcker's method. The bladder was thus completely extraperitonealized and the right ureter was exposed. The bladder was next opened at the vertex, and a papillomatous tumour, sessile and about the size of a betel nut, was found in the trigone just close to the opening of the right ureter (figure 4). The mucosa surrounding the tumour up to the ureteral opening was hyperæmic and oedematous indicating infiltration. The ureter was found to be quite free on passing a catheter. The posterior wall of the bladder was mobilized and the ureter was freed from its surrounding tissue for about four to five inches (figure 3). As the tumour was close to the right ureteral opening, and the surrounding mucosa

was involved, the right ureter was cut near its attachment to the bladder and kept aside with a catheter passed through it. The portion of the trigone occupied by the tumour and the surrounding portion, half an inch on all sides, were completely removed with a knife. There was a good deal of difficulty in closing the gap thus formed in the trigone, on account of the narrowness of the space. The detached ureter was brought inside the bladder through a separate opening in its wall and re-implanted in its new place. A catheter was kept inside it and it was brought out through the abdominal wound. The bladder wall was found to be rather badly torn in the course of these manipulations and small tags had to be cut away to make the margin of the tears even. The tears were all closed leaving a small gap for a rubber drainage tube inserted into the bladder cavity and for the ureteral catheter. A drain was placed in the cave of Retzius. Urine drained freely through the tube in the bladder and also through the ureteral catheter. On the fourth day the ureteral catheter came out. A catheter was introduced through the urethra on the fifth day and kept there for about four days. On the tenth day the patient was able to pass a little urine himself through the urethra. Gradually he was able to pass more and more urine but the retentive power of his bladder was limited, so he had to pass urine every three or four hours. But this condition also improved gradually. On the fifth day he complained of some pain in the right kidney which disappeared within twelve hours. He was discharged completely free from all symptoms after about four weeks. The operation was done in September 1932 and at present he is enjoying good health and earning his livelihood as a fruit seller. The tumour was found to be an epithelioma, on pathological examination.

Case 2.—Diagnosis—stone in the bladder, and a stone in the right ureter at the level of the fourth lumbar vertebra.

N. G. A., male, aged 36, complained of difficulty and pain during micturition for a year and a half, with passage of pus. The right epididymis was very tender and the patient had all the symptoms of a severe attack of cystitis. The general condition was far from satisfactory. An ordinary skiagram and pyelography revealed two small stones, one in the bladder and another in the right ureter at the level of the fourth lumbar vertebra (figure 5).

Fig. 5.—Skiagram (of case 2) showing one small stone in the right lower quadrant of the pelvis and another stone at the level of the body of the fourth lumbar vertebra.

The abdomen was opened by a vertical incision. The bladder was extraperitonealized according to Voelcker's

HERNIAS OF THE LARGE INTESTINE : WITH SPECIAL REFERENCE TO SLID- ING HERNIAS

By SUKH DAYAL, M.B., B.S. (Alld.), D.I.O. (Lond.)
D.O.M.S. (Lond.), F.R.C.P. & S. (Glas.), F.R.C.S. (Edin.)
Lecturer in Surgery, Medical School, Agra

ANY portion of the large intestine, namely the cæcum, ascending, transverse, descending or

(Continued from previous page)

method, and the peritoneal cavity was carefully closed and isolated by means of abdominal towels. The bladder was then opened at the vertex and the stone removed.

Next, the ureter was followed up along its proximal course by lifting up the posterior parietal peritoneum from the posterior abdominal wall. A small tear occurred in the peritoneum during this manoeuvre, which was at once closed. There was a good deal of difficulty in reaching the stone. However it was located with the finger tips at the level of the fourth lumbar vertebra and was with some effort milked downward and removed by an incision in the wall of the ureter. The incision in the ureter was not closed.

Next a drainage tube was inserted in the area behind the posterior parietal peritoneum and brought out through a stab wound in the right flank. The opening in the bladder was closed and a rubber tube inserted in it for draining the urine. The abdominal wound was closed with another tube in the extraperitoneal space behind the bladder. Urine drained freely from the tube inserted through the stab wound in the flank and also from the bladder tube. The tube in the flank was removed after about eight days and urine stopped coming through the opening after about fifteen days. After three weeks the bladder tube was removed and a urethral catheter inserted. The patient's general condition steadily improved. The pus in the urine stopped after the administration of intravenous acriflavine.

Comment

(1) Extraperitonealization of the bladder gave good access to the trigone facilitating complete removal of the malignant tumour with some portion of the surrounding area.

(2) The process of extraperitonealization is a comparatively easy one and interference with the peritoneal cavity is negligible.

(3) In the two operations reported above, the bladder was distended with fluid at the beginning of the operation causing stretching and thinning of the walls which caused tears in the process of detaching the peritoneum. So the bladder should be washed out at the beginning of the operation and left empty.

(4) In the second case, but for the above method, the patient who was very much debilitated would have had to undergo two operations, one for the stone in the bladder, either litholapaxy or suprapubic cystotomy, and another for ureteral stone situated fairly high up, which would have required a lumbar incision. By the above method the patient had very little shock and convalescence was uneventful.

the sigmoid colon, can form a part of the contents of a hernial sac, in the same way as the small intestine does, but of special interest are the hernias of the cæcum, and of the ascending and the descending colon, when they slip down behind the peritoneum leading to the formation of the so-called 'sliding hernias'.

B. P., aged 40 years, was admitted on 29th August, 1933, with a left inguinal hernia about the size of a coconut, of 8 years' duration. The inguinal canal admitted three fingers, the mass was tympanitic on percussion; on reduction some of the contents went back into the abdomen with a gurgle, but a part of the swelling still persisted and remained tympanitic. The patient had had a chronic cough for about 3 years. After being treated for his cough he was operated upon for his hernia on 10th October.

On operation, the sac which seemed to have fleshy adhesions anteriorly and medially was found to contain the ileum and the appendix, and there was extreme difficulty in reducing the contents completely, and in clearing the sac up to the neck, particularly on the medial and anterior aspects. On attempting to liberate the sac on its inner side a doughy mass could be traced downwards into the scrotal bag and over it ran a longitudinal band resembling the ductus deferens adherent to the hernial sac in the ordinary way. On separating the mass from the scrotal bag it was found to be a loop of the large bowel lying outside the hernial sac. The portion of the loop adjacent to the sac was narrower than the rest and was firmly adherent to the sac on its posterior and outer aspect for a short distance.

Evidently the case was one of sliding hernia of the cæcum and the ascending colon. The lower part of the ileum, the appendix and the cæcum can easily form the contents of an inguinal hernia on the right side and the sigmoid colon on the left, but the presence of the cæcum and ascending colon in an inguinal hernia on the left side, particularly extraperitoneally, is uncommon, and it is no wonder that such a condition affords an unpleasant experience to the surgeon. Such cases are difficult to deal with and should be taken up cautiously by a surgeon of limited experience. The diagnosis of such a condition beforehand is, however, almost impossible except where the coverings of the hernia are very thin, so that the contents may be recognized by palpation, and the hernia is a large one. The fact that in the above case only some of the contents could be reduced with a gurgle, leaving behind a doughy mass still tympanitic, should have roused suspicion, because in such a case, the irreducible tympanitic mass could be none other than a loop of the bowel adherent inside the sac or an extraperitoneal loop of the cæcum, ascending or descending colon, always so difficult of reduction; the advisability or not of undertaking operation for such a condition should be seriously considered.

The occurrence of the cæcum and ascending colon in an inguinal hernia on the left side is rather hard to imagine, but is quite a possibility when we consider the development and transposition of the intestinal tract in the foetus. In the foetus, the midgut from which are developed the small intestine and the large intestine

up to the transverse colon, for the most part lies outside the abdomen in the root of the umbilical cord, at one stage of development. This is in the form of a loop with a dorsal mesentery, in the substance of which runs the superior mesenteric artery, from the aorta to the summit of the loop, dividing it into a pre-arterial and a post-arterial segment. During the fifth week a small diverticulum appears upon the post-arterial segment to form later on the cæco-appendicular region. As the embryo grows, the extra-abdominal loop retracts into the abdominal cavity, and the pre-arterial loop, from which is developed the small intestine, occupies the right side of the abdomen, and the post-arterial loop, from which is developed the large intestine including the cæcum and the ascending colon, occupies the left half. As growth advances, the small intestine grows downwards and to the left behind the mesenteric vessel, and due to the same impulse the cæcum crosses the middle line to the right finally reaching its resting place in the right iliac fossa. When the cæcum and the ascending colon have reached their normal position, the former to a very small, and the latter to a very large, extent become denuded of the peritoneum on the posterior aspect, partly because the bowel outgrows the serous covering and partly because the lateral walls of the abdomen as they grow, pull with them a part of the peritoneum from off the ascending colon. During this process of development the cæcum and the ascending colon may not be properly transposed to the right side, and thus may remain on the left side of the abdomen and may also retain the mesentery; therefore the cæcum and the ascending colon may enter not only the right inguinal hernia but also the left, and when also underdeveloped will find entrance more rapidly through the inguinal canal. Thus the presence of the cæcum and the ascending colon in the left inguinal hernia can be accounted for in one of the following ways:—

(1) By want of perfect transposition in the process of development.

(2) By unusual length of the mesentery due to defective development.

(3) By a combination of the above two conditions.

(4) By a process of 'pulling' and 'pushing' mechanism.

The mechanism of 'pulling' and 'pushing' is particularly at work in producing the extraperitoneal sliding hernias. The 'pulling' mechanism is at work in large hernias and here the ascending colon is accompanied by other viscera, *viz.* the cæcum, the appendix and even the small intestine. The 'pushing' mechanism is at work in small hernias and these are entirely devoid of sac and will be very puzzling.

Treatment.—The treatment of hernias of the large intestine where the loop of bowel has an almost complete covering of the peritoneum in no way differs from a hernia of the small intestine; here the contents can be easily reduced

and the sac excised. But the treatment of sliding hernias of the large intestine is at times a matter of exceptional difficulty. The surgeon must be thoroughly acquainted with all the forms and possibilities of such a hernia, because serious and irreparable damage may be done by ignorant surgery. When the cæcum and ascending colon herniate extraperitoneally, they sometimes undergo a partial rotation, so that the posterior surface of the bowel, which is without peritoneal covering, may form the anterior and the outer wall of the tumour, and as such may be mistaken for the sac covered with the various strata, and, one of the tænia coli simulating the ductus deferens adherent to the sac, the latter may be incised with disastrous results. In small extraperitoneal hernias caused by the 'pushing' mechanism, the bowel is devoid of sac, but the loop of the bowel is so small that it can be pushed back into the retroperitoneal space with a little blunt dissection, and then deep sutures are passed taking care that the gut is replaced into its normal position while the sutures are being tied. Sliding hernias, caused by the 'pulling' mechanism, are usually large. On opening the sac, while most of the contents can be reduced it is found that a small piece of the intestine resists all efforts at reduction. By enlarging the incision in the sac and examining the interior, it is found that the irreducible loop of the bowel has perhaps a longitudinal muscular band on it as well as some appendices epiploicæ. In this variety of the hernia, the nutrient vessels of the gut are usually pulled on with the gut. Separation of the peritoneal sac will naturally deprive the bowel of its blood supply and with the attendant danger of gangrene and perforation. The way in which the operation for such a hernia is performed is as follows:—

The sac and the herniated intestine along with its blood vessels is lifted up from the posterior part of the hernial bag without seriously damaging the blood vessels of the herniated bowel. If the sac and the herniated loop of bowel are now lifted vertically up, it will be found that the sac falls on either side of the bowel, covering its nutrient vessel. The sac is now stitched here and there by a few stitches, thus forming a sort of mesentery for the bowel, and then there will be no difficulty in reducing the portion of the intestine. The remaining part of the sac is closed by a running suture and the usual radical operation is completed.

Another way in which this condition can be dealt with is as follows:—Having recognized the nature of the hernia, the inguinal wound is packed with gauze and the abdomen is opened through a separate incision. With the patient in the Trendelenburg position, the colon is pulled up into the abdomen and colopexy done to fix it up to the posterior abdominal wall. The abdominal wound is closed,

NOTES AND OBSERVATIONS ON 'INFANTILE BILIARY CIRRHOSIS'

By N. G. PANDALAI, M.B., B.S., D.T.M.
Medical College, Vizagapatam

[Received for publication on 1st June, 1933]

Idiopathic enlargement of the liver, commonly known as infantile biliary cirrhosis, is a disease of childhood which presents considerable difficulties, both in diagnosis and in treatment. The literature on this subject is exceptionally scanty and scattered. In this paper, which is based on the clinical observations on a few cases and the detailed notes collected from various sources, it is my idea to present in a connected form the important points associated with the disease.

Infantile biliary cirrhosis, infantile cirrhosis of the liver, or infantile liver, is a definite disease entity of infants characterized by an insidious onset, a rather slow course, enlargement of the liver and spleen, jaundice, late ascites, and an invariably fatal termination. It cannot be a form of kala-azar as Castellani and Chalmers (1919) have suggested, as it is found in many parts of India where kala-azar does not exist.

History.—No mention of the disease is made in any of the older writings. Sen (1887) first described it and mentioned it as one of the causes of hepatic enlargements in infancy. In the following year Gibbons (1891) described in detail the morbid anatomy and pathology of the disease. Mukherji's (1922) booklet on the subject is the next notable contribution. Since then, a few papers on the subject have appeared, mostly dealing with its aetiology and treatment.

Geographical distribution.—It is noteworthy that the disease has not been reported from outside India except one similar case from Mexico and a few cases from North China. Whether the aetiological factors operating are particularly Indian or whether the disease is merely not reported from other countries, it is yet difficult to say. In India, cases have been reported mostly from Calcutta, Bombay, Madras and the United Provinces. It is common in Malabar, Travancore and Mysore. Mukherji (1922) says that the disease is more prevalent in the cities and the *mofussil* towns than in the villages. Possibly this is due to the greater opportunities for accurate observation in the cities, and not to any really restricted prevalence.

Aetiology.—The disease is common among the Hindus, very much less among the Moham-medans, and rare among the Anglo-Indians. It does not make any distinction between castes. The children of the rich and the middle classes are relatively more prone to it than

those of the poor and the labouring classes. Overfeeding may have something to do with this disparity. The disease tends to run in families. The first child is said to be the more frequent victim. Probably more male children are affected than female. It is rare before six months and after three years of age. Usually it begins during the time of dentition or between the sixth and the eighth months. In many cases the mother will have already conceived by this time. The greatest death rate is between nine months and two years.

A number of theories has been advanced from time to time regarding the cause. Many of them do not bear close scrutiny. The disease is restricted to India practically. Such a limited distribution argues against almost all the theories hitherto propounded. Neither alcoholism in the parents, nor syphilis seems to have anything to do with the aetiology. If alcoholism in the parents had any part in the causation of the disease it should have been prevalent in other countries as well, where alcohol is much more freely used. Many cases of infantile biliary cirrhosis are known to occur in children whose parents are unquestionable teetotalers, and, *per contra*, the disease is not particularly common amongst children of parents of very intemperate habits. Besides, the pathological changes in the liver in this disease are nothing like those of an alcoholic liver, except the enlargement. Syphilis in the parents can also be ruled out. The Wassermann reaction of the blood is repeatedly negative in the patients as well as in the parents. It is true that the Wassermann test is not positive in a hundred per cent of cases of hereditary syphilis, but it is difficult to believe that *all* the cases of infantile biliary cirrhosis are cases of infantile syphilis with a negative Wassermann reaction. No other evidence of congenital syphilis is present in these cases of hepatic enlargement, nor are the features of the two diseases identical. The urban distribution and the comparative infrequency of infantile biliary cirrhosis in rural areas are against a malarial aetiology. Infantile biliary cirrhosis is fairly common in places like Malabar where kala-azar is unknown, while it is not seen more commonly in the kala-azar endemic areas than in other places. Besides, no case of infantile biliary cirrhosis has been reported from the Mediterranean area where kala-azar is almost exclusively confined to children. Clinically also these two diseases differ. Amyloid degeneration, infection, bacterial or parasitic, or ascending cholangitis have all been suggested as causative factors, but the available evidence does not support any of these.

Deficiency of vitamin C.—This in the infant's dietary has been adduced as the cause of the disease, or in other words that infantile biliary cirrhosis is a variant of infantile scurvy. It is true that boiled cow's milk or some kind of artificial food deficient in vitamins may form the infant's diet when the mother's milk is not available, or becomes deficient in quantity or

(Continued from previous page)

the redundant portion of the sac in the inguinal wound is freed and excised and the operation finished as is the usual radical operation.

quality, from pregnancy or some other cause, but, clinically, infantile biliary cirrhosis is quite different from Barlow's disease. Also, Mukherji's experiments with boiled milk on young guinea-pigs do not tend to support this view. Others believe that vitamin deficiency may operate through the mother, in the first place, by interfering with the normal development of the endocrine system of the foetus and later, in the post-natal period, by depressing her mammary secretion. If such a handicapped child is overfed after birth, infantile biliary cirrhosis results. Other suggested causes, such as the deficiency of fat and sugar in the cow's milk on which the infant is fed, deficiency of vitamins in cow's milk due to the poor quality of the animal's fodder, and excess of sugar content in the mother's milk, are mentioned here, if only to show how divergent are the views about the aetiology of the disease.

Mukherji suggests that infantile biliary cirrhosis may be the expression of an overworked and exhausted liver, as a result of gross overfeeding or feeding with unsuitable diet. Early administration of starchy food may also play a rôle according to this observer. The history of these cases very often reveals dietetic irregularities, such as irregular feeding, too frequent feeding and feeding with unsuitable articles of diet, such as overboiled cow's milk, undiluted cow's milk, or rich and farinaceous delicacies. Also the infant is fed as often as it cries. All these lead to overfeeding. Early conception of the mother and consequent early weaning are antecedent conditions in many instances. Again, in not a few cases the mother may have some disease or her food may be unbalanced and defective in quality. In all these circumstances artificial feeding is begun too early when the child is still very young. It is doubtful if overfeeding on an excessive carbohydrate diet alone can cause cirrhosis of the liver. Probably dietetic irregularities play a part, but not the sole part, in the aetiology of the disease.

Another theory advanced is that infantile biliary cirrhosis is due to a toxic irritation of the liver. The toxins are either transmitted through the mother's milk, or formed and absorbed from the child's gastro-intestinal tract. It is true that the liver is a very important detoxicating organ and constitutes the first line of defence against the toxins absorbed through the portal channel; but if the oncoming toxin is in massive doses this toxophylactic mechanism is very likely to break down. There is evidence of irritation as shown by the pathological changes of degeneration of the liver cells and proliferation of the connective tissue. This view has been refuted on the ground that irritants absorbed through the portal circulation usually cause a multilobular cirrhosis and not an intralobular cirrhosis and that the same cause does not give rise to different pathological changes in the same organ. This refutation does not take into consideration the nature and the

conditions of action of the irritant, nor the age factor which substantially modifies the type and the degree of tissue response. Also, the infant with its peculiar anatomy and physiology shows a greater susceptibility to the disease-causing agencies than the adult.

Probably there are two factors operating, one, a gastro-intestinal toxæmia resulting from an early faulty feeding, and the other, a congenitally insufficient liver with inadequate defence powers. The liver, as mentioned above, serves a very important antitoxic function, and if this is below par any toxic agent reaching the organ becomes relatively more potent. The digestive system of the infant is not adapted for utilizing adult diet. Faulty diet may cause a mild gastro-intestinal disturbance, easily curable in the beginning. The disturbance may be in the form of an imperfect digestion or a perverted digestion. The normal flora of the intestines may become abnormal in the altered surroundings or there may be a fresh invasion of the gut by some pathogenic organisms. Products of abnormal digestion and bacterial activity are liberated and absorbed in massive quantities. For a time the liver meets the situation and does not bring the intoxication into symptomatic prominence, but eventually it breaks down. It is conceivable that in some infants the organ is functionally defective, either because of some developmental error or some hereditary tissue inferiority. Heredity cannot be ruled out on the ground that the onset of the disease is only a few months after the birth. The inferiority may be in the parenchyma, in the reticulo-endothelial system, or in both. This latter system is being recognized more and more as a very important defence mechanism. Some abnormality in the vascular system or nerve supply of the organ as a possible background is also worth considering. It is also conceivable that there is a deficiency of some hitherto undetected antitoxic secretions of the liver.

None of the theories mentioned above satisfactorily accounts for the causation of the disease and the fact remains that the true nature of the aetiology has yet to be unravelled. Detailed studies and observations on the epidemiology of the disease may probably shed further light on this point.

Pathology.—The abdomen is enlarged, usually more in the right hypochondrium. The liver is enlarged and smooth, and as contraction sets in the anterior edge becomes thin and sharp. Jaundice appears early and gives a 'direct delayed' van den Bergh reaction, pointing to an early damage of the liver cells. The early derangement of the liver function is also shown by an early positive lævulose tolerance test. The spleen is enlarged. Towards the end ascites appears with prominent abdominal veins and other signs of portal obstruction. Œdema of the lower extremities is present in the advanced stages. Blood culture may be positive in many cases, probably due to secondary invasion.

B. faecalis alkaligenes, *B. lactis aerogenes*, or *B. coli* has been isolated in several instances. A tendency for hyperglycaemia without glycosuria has been reported by some observers. There is marked anaemia in the advanced cases with a lowered fragility of the red cells. Leucocytosis with a high lymphocytic count is a feature of the second stage, but the normal blood picture in infancy and early childhood, it must be remembered, is markedly lymphocytic in character. The ascitic fluid is clear and is only a transudate. It is deeply bile-stained. The urine is scanty and high coloured. It is acid in reaction and the specific gravity varies. Bile and urobilin are present in varying amounts according to the stage of the disease.

The pathological anatomy was studied by Gibbons (1891). The liver is enlarged and of normal shape in the early stages. It is still larger than normal and normal in shape even after contraction has set in. The organ is smooth in the early stages, but later shows a finely-reticulate yellowish appearance and a thinned out anterior edge. There is no evidence of perihepatitis or thickening of the capsule at any stage, but thickening of the capsule without any evidence of perihepatitis has also been reported. The cut surface is pale, granular and fairly tough in the early stages, but as the disease advances it becomes deeply stained, granular and very tough in consistency. The gallbladder is shrunken and the common bile duct is patent. The former contains, in advanced cases, a small quantity of pale gelatinous mucus in no respect resembling normal bile. Microscopically, there is evidence of early irritation of liver cells as shown by the cloudiness and granularity of the protoplasm and the multiplication of the nuclei. The columnar arrangement of the liver parenchyma is being lost as it is cut off into irregular groups by the proliferating intercellular connective tissue. The young fibroblasts are loosely arranged while there is no particular localization within the lobule for this proliferative process. The degenerative changes in the parenchyma seem to be primary and the connective tissue proliferation is in the nature of a replacement fibrosis. The portal sheaths also show proliferative changes as evidenced by the round-cell infiltration and the multiplication of blood vessels. Fibrous strands are seen extending a short distance between the lobules also but not encircling them. The intercellular fibroblastic reaction is not due to an extension inwards of the changes without, as happens in true biliary cirrhosis, but precedes the latter. Formation of new bile ducts in the newly-formed interlobular connective tissue is also discernible from the early stages. In the advanced cases the normal arrangement of the liver cells is almost lost. In many places the islets of liver parenchyma are completely replaced by a structureless debris while at others the liver cells are in an advanced stage of degeneration, as evidenced by the granularity of the

protoplasm, the contained pigment particles, and oil globules. Here and there, there may be a few healthy cells. The newly-formed connective tissue has increased in amount and matured into firm fibrous tissue. The fibrous tissue between the lobules now completely encircles each lobule. Proliferation of bile capillaries is a well-marked feature of this stage and is seen not only in the portal areas but also within the lobules where the liver cells have degenerated and disappeared. This feature in the pathology of the disease is regarded by Gibbons as a natural attempt at repair and regeneration of the liver parenchyma, a view originally suggested by others in the case of biliary cirrhosis. Gibbons regards the liver condition as a type of biliary cirrhosis. But as the primary changes are in the liver cells and the other changes are only secondary, Mukherji and others consider that Gibbons' view is untenable and that the condition cannot be termed a real biliary cirrhosis. They suggest the name 'intercellular hepatic cirrhosis of infants' for the disease.

The spleen is enlarged during the contracting stage. Its reaction presents the appearance of passive congestion. The kidney may show evidence of parenchymatous nephritis. Enlargement of the lymphatic glands is not noticed.

Symptoms.—The onset is insidious and the disease is fairly advanced by the time something has aroused the suspicion of the parents that all is not well with the child. During this initial stage the child is active enough and takes its food as usual. It may even show a voracious appetite. An occasional vomiting or slight nausea is not such an uncommon feature of infancy as to cause any suspicion. Nothing gives a clue for diagnosis in this stage. A slight puffiness round the eyes and swelling about the ankles on waking up in the mornings may be looked for in the early stages as suspicious of the disease. So also a deposit when the urine passed by the child has evaporated off.

The second stage begins with noticeable enlargement of the upper part of the abdomen. The appetite is impaired or there may be a depravity of appetite, the child eating all sorts of things and craving for all kinds of sweets. Nausea and vomiting increase in frequency and intensity. Constipation becomes worse and persistent. An intelligent mother may have also noticed a loss of normal colour of the stools. The child is thirsty, feverish, more and more irritable and sleepless. Burning sensation of the hands and feet may be complained of by older children. Diagnosis is made mostly in this stage which, in a good number of cases, is by accident when the doctor is called in for some other complaint. On examination, a uniform and painless enlargement of the liver is noticed. The organ is firm and hard with a smooth surface. Rounded and prominent, the lower margin may reach the umbilicus or even beyond. The spleen may or may not be palpable in this stage. Prominent veins are seen on the abdomen. A

slight yellow discoloration of the conjunctivæ may be noticed. There is no emaciation, but a peculiar muddy complexion of the skin is a marked feature. Low irregular fever is a feature of this stage, the temperature rising towards night, but seldom beyond 100°F. Sometimes there may be only a morning rise. The temperature may be irregular, intermittent, or low remittent in type. The cause of this fever has been variously explained as being due to gastro-intestinal upset, auto-intoxication, or secondary blood infection. The motion is white and offensive. Now and again it may show slight colour varying with the liver condition. Microscopically, there are many fat globules, undigested debris, and a seething bacterial flora. Urine is scanty and high coloured, acid in reaction and of varying specific gravity. Casts are rare, but degenerating leucocytes and epithelial cells are present almost always. A catheter specimen may grow organisms, which may or may not have been excreted by the kidneys. Anæmia is not marked, but the leucocytes are increased in number, 12,000 to 20,000 per c.mm., with a lymphocytic predominance. The van den Bergh reaction is 'delayed direct' and liver efficiency tests show damage. Bronchitis, broncho-pneumonia, or enteritis may complicate the course of the disease and may even end the scene. This stage lasts from three to six months.

Third stage: In this stage the liver has begun to contract, and, as the contraction advances, evidence of portal obstruction supervenes. Oedema begins to appear and the superficial abdominal veins become prominent. Anasarca and effusion into serous cavities are then added to the picture. The contraction of the liver may be associated with pain, and its margin becomes sharp and well marked. The spleen is very much enlarged. Jaundice is deepening and the skin is intensely yellow, dry and irritating. Emaciation is not apparent. Urine is scanty and yellow. Constipation continues unless there is a complicating enteritis. Stools are large, offensive and white. Anæmia is marked and leucocytosis continues. There may be hyperglycæmia but no glycosuria. Respiratory complications may appear as in the second stage. Temperature may be high, 102° or 103°F. or even higher, irregular, hectic or even continuous. Hæmorrhages, when they occur, are terminal and take place into the gastro-intestinal tract, the genito-urinary tract or the skin. In one case the vomited material was pure blood. In the majority of cases death is due to cholæmia, the child losing interest in the surroundings, becoming more and more apathetic, drowsy and finally comatose. The type of coma is peculiar in that it resembles natural sleep as was described in adult cirrhosis by Rowntree (1930). Sometimes convulsions precede death. Rarely death may be due to profound cachexia or to some intercurrent disease.

Diagnosis.—Diagnosis is seldom made in the early stage, a history of infantile liver in other

children of the family, the age of the patient—between 6 months and 2 years, the insidious onset, the painless enlargement of the liver, the leucocytosis, the persistent constipation and clayey stools, the irregular fever, the subicteric tinge of the conjunctivæ, and the sallow complexion all form a definite syndrome, which, in the absence of evidence of other diseases, gives a clear ground, in the second stage, to arrive at a correct diagnosis. In the third stage, in addition to the above, the presence of enlargement of the spleen besides the liver, the signs of portal obstruction, the deepening jaundice, the offensive white stools, and the scanty bile-containing urine make the diagnosis easy.

It has to be distinguished from a number of conditions. The infant liver is quite palpable normally and weighs proportionately more than the adult liver.

Congenital syphilis.—Infantile biliary cirrhosis can be differentiated from this by the negative Wassermann test in the patient and the parents, the absence of stigmata of congenital syphilis in the child, the uniform enlargement of the liver instead of the irregular enlargement of syphilis, and the absence of fever.

In catarrhal jaundice the enlargement of the liver is slight, the organ is tender and soft, jaundice appears early, preceded generally by symptoms of acute gastro-intestinal catarrh or some acute infection such as influenza, and the jaundice disappears rapidly under treatment.

Rickets is not common in Indian children and there are distinguishing bone changes in it.

Kala-azar is not common in children under three years, the enlargement of the spleen is greater and earlier in this condition, and leucopenia is the rule.

Malaria does not present any serious difficulty; its sudden onset, high fever coming on in paroxysms, enlargement of the spleen, and the positive blood findings make it easy.

In familial acholuric jaundice several members of the same family may be affected at the same time and there is enlargement of both the liver and the spleen presenting real difficulty; but there is no bile in the urine, while there are positive blood findings with increased fragility of the red cells, and the disease runs a chronic course marked by remissions and exacerbations.

In von Jaksch's anæmia, the spleen is enormously increased in size; there is no jaundice and the blood shows a severe grade anæmia and myelocytes. It is also a disease of the poorer classes.

Other conditions.—As a disease entity, Hanot's cirrhosis does not exist according to Hurst, and, even if it does, it is an exceedingly rare condition, occurring in older children, running a very chronic course, and at intervals showing exacerbations of temperature with deepening of the jaundice and increasing pain over the liver area. Other conditions such as downward displacement of the liver, giardiasis, Gaucher's

disease, and amyloid disease do not really confuse the diagnosis.

Prognosis.—There is a general belief, even among the laity, that the prognosis is gloomy. This seems to be an extreme view; the prognosis depends upon the stage at which the disease is recognized. Mukherji gives a death rate of 63 per cent, but it is probable that some of the cases that have been reported as cured were those of congenital syphilis in which condition treatment with mercury is very much more effective. If untreated, the disease runs its fatal course in 3 to 18 months, with 6 weeks and 2 years as the outside limits. Earlier onset, a more rapid course, jaundice, and œdema are all unfavourable. An early diagnosis and treatment before the liver has begun to contract offer the best chance.

Treatment.—Probably the disease can be prevented to a large extent by the careful dieting and hygiene of the mother during pregnancy and the lactation period, and of the infant when it is weaned. Efficient treatment of the mother for any disease during pregnancy or afterwards is called for in any case. Some observers regard the administration of liver extract in the early stages of pregnancy as a prophylactic.

No treatment is of any avail in the advanced stages. If the case is seen early, change the surroundings completely and remove the child to a wet nurse. If a wet nurse is not available substitute good cow's milk, properly humanized. Goat's milk and ass's milk are said to be more suitable for the infant. Feeding must be regular and in moderate amounts. Milk must be supplemented with orange or lemon juice daily in half-ounce doses well diluted in water. Plenty of sunshine and open air are very important. With early and efficient treatment recovery may take place in 6 to 10 weeks.

Hydrargyrum cum creta in $\frac{1}{2}$ to 1 grain doses, according to age, may be given as an adjuvant treatment. It must be freshly prepared. *Kalmegh* is an old indigenous drug used in this disease. It is a powerful hepatic stimulant and probably regenerative. It also relieves the constipation. To be effective, fresh extract must be given three times daily in doses of 5 to 20 drops according to age, and well diluted in water. *Liquor kalmegh* co., which contains some of the other hepatic stimulants as well, is also well spoken of. Extract of liver is advocated both for the mother and the patient. Vegetable cholagogues such as taraxacum, ipecacuanha, or rhubarb are said to be good.

Saline purgatives or glycerine enemata are called for in obstinate constipation. Œdema may be relieved by saline purgatives. Mercury preparations, such as salyrgan, are not advisable on account of the kidney condition. Paracentesis of the abdomen is better avoided, unless the pressure symptoms are very distressing.

Short clinical descriptions of six illustrative cases, all of which ended fatally, are given below:—

Summary of case reports

Case 1.—A Hindu female child, 9 months old, was seen with fever and enlargement of the abdomen of 2½ months' duration. Case history revealed a lack of appetite from the 6th month, with subsequent onset of wasting and swelling of the abdomen; there was constipation from the 7th month the patient passing whitish stools occasionally, and fever for 3 days in the 8th month. She was the first child and her diet consisted of the mother's milk supplemented with Nestle's milk food and arrowroot jelly. There was no irregularity in feeding nor overfeeding. The parents belonged to the upper class and were lacto-vegetarians and teetotalers. They were healthy and denied any history of syphilis. Their diet, as detailed by them, seemed to have no deficiency of vitamins in it. The mother suffered from bad nausea and vomiting throughout her pregnancy period.

The child did not show any constitutional deformity, but was slightly wasted and inactive; the temperature was 101°F. and the pulse slightly accelerated, the conjunctivæ were yellow, and the skin of an earthy hue, and the abdomen was uniformly enlarged. The liver was palpable reaching the umbilicus, rather hard and smooth, but not tender. The spleen also was palpable. The urine was staining the napkin yellow and the motion was pasty, clayey, offensive and without any macroscopic blood or mucus. Her condition grew worse with marked evidence of portal obstruction appearing in the 10th month. She died in her 11th month. General anasarca developed a week before death, and hæmatemesis and hæmaturia in the last 24 hours. The temperature continued to oscillate between 99°F. and 105°F. till a few hours before death.

Case 2.—A Hindu male child, aged 17 months, with swelling of the abdomen of 5 months' duration. He was apparently healthy for the first 6 months. Irregular fever, occasional sleeplessness and vomiting, loss of appetite, constipation and whitish motions were the points of interest in the case history. The child's urine used to leave on the floor a whitish deposit after evaporation. He was the second child, the first having died on the third day after birth. The parents were non-vegetarians, teetotalers and from the lower middle class. Both were healthy and gave no history of syphilis; the mother was then 2 months' pregnant. Mother's milk formed the child's food with the addition of boiled and diluted cow's milk from the 7th month.

A subicteric tinge of the conjunctivæ, a muddy complexion, puffy face, swollen eyelids, uniform enlargement of the abdomen with distended veins and everted umbilicus and oedematous shiny lower extremities constituted the clinical picture. A soft systolic murmur at the apex and basal crepitations in the lungs were present. The liver and the spleen were uniformly enlarged, hard and smooth, but not tender, the former extending 3 inches and the latter 2 inches below the costal arch. There was free fluid in the abdomen. The motion was bulky, semi-solid, white and very offensive; the urine was dark yellow in colour. The child went slowly downhill and died at the 24th month in spite of all kinds of treatment.

Case 3.—This was a Brahmin male child of 14 months age, with swelling of the abdomen of 9 months' duration, a slight yellow colour of the conjunctivæ and the skin, fever and cough. Save for a capricious appetite, constipation and occasional fever, the history was not important. He was the 6th child of the father and first of the mother. All the 5 children by the first wife were alive and well. The parents came from the upper middle class, were healthy and denied any history of venereal disease. The mother was then 5 months pregnant. Because of the insufficiency of her milk the

child was also getting sago jelly from the second month. There was much irregularity in feeding.

The child was undersized, thin and emaciated; it had a distended abdomen with prominent veins and splayed out costal margins. Oedema round the ankles was noticeable. The temperature was 100.5°F. and there were signs of mild bronchitis. Both the liver and the spleen were smooth and palpable, the former 4 inches and the latter 3 inches below the ribs. The stools were semi-solid, white and offensive, and the urine scanty and intensely yellow. The child lingered on for 6 weeks more, broncho-pneumonia developing a few days before the end.

Case 4.—The younger sister of the above patient came under observation for fever at the 9th month and was cured. As a precaution this child was getting fresh diluted cow's milk instead of sago jelly. Three months afterwards, the child was again seen, this time with a suspicious enlargement of the abdomen. The liver was palpable 1½ inches below the costal margin, but the spleen was not felt. The child died at its 13th month with intense jaundice, a markedly enlarged abdomen and anasarca.

Case 5.—It was a male child, 16 months old, showing a uniform distension of the abdomen, oedema of the lower extremities, fever and jaundice. The abdominal swelling was of 5 months' duration; it had had jaundice and oedema for 3 weeks and fever for 5 days. The patient's motions had been abnormal in colour from birth. Failing appetite, irregular fever, sallowness of complexion, peevishness, sleeplessness and slight loss of flesh were the points in the history. He was the first child of Indian Christian parents, belonging to the upper middle class. The husband was the maternal uncle of the wife. The latter's constitution was delicate and she had had an abortion at the 4th month of pregnancy. She had plenty of milk and the child was also getting orange juice daily. No irregularity of feeding, nor overfeeding was reported.

The temperature was 100.5°F. and pulse 116. Signs of a decompensated liver were already there. The liver and the spleen were enlarged and there was no tenderness nor pain. The blood was anæmic with a high white cell count, the small lymphocytes forming 41 per cent. The Wassermann reaction on the patient as well as the parents' blood gave negative results. The aldehyde (kala-azar) test and the agglutination test against dysentery organisms were also negative. The pasty white motion showed many fat globules, undigested debris, bacteria and a few yeast-like cells. The dark-green urine contained urobilin and bile pigments, and the deposit phosphate crystals, a few epithelial cells and many non-motile bacilli. *B. lactis aerogenes* was grown from the urine. The child's condition got worse and he died after 2 months.

Case 6.—A one-year-old female child of a middle class Brahmin family was brought with swelling of the abdomen of 5 months' duration. She was the second child, and the first and the third were still alive and healthy. The points of interest in this case are that from its birth the child was getting, every other day, castor oil with small doses of a bazar medicine containing mercury, and after the appearance of the swelling the child was given a *kalmegh* preparation for three months and later intravenous antimony. The blood was watery, anæmic and showed no parasites. There was a leucocytosis with 57 per cent neutrophils, 37 per cent lymphocytes, 2 per cent large mononuclears, 2.5 per cent eosinophils, 1 per cent myelocytes and 0.5 per cent mast cells. The Wassermann reaction and the agglutination test were negative. There was a trace of albumin in the urine from which *B. fecalis alkaligenes* was isolated. The condition of the patient became worse and worse, and she died in her 14th month.

STUDIES ON THE ACTION OF QUININE IN MONKEY MALARIA

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

Professor of Pharmacology

and

B. M. DAS GUPTA, L.M.P.

Assistant Professor of Protozoology,
School of Tropical Medicine, Calcutta

KLIGLER and Mer (1931 and 1933) have called attention to the relationship between host immunity and chemotherapeutic efficacy of chinoplasmine in malaria and this relation probably applies to other antimalarial drugs also. They have suggested that the therapeutic value of a drug should be checked by its effects on children below 6 years of age as they are less capable of developing a resistance or immunity to malarial parasites than those above this age. There may, however, be difficulties in the way of carrying out such tests. It has been shown that the plasmodium in monkeys, *P. knowlesi*, produces a very intense and virulent infection in *Silenus rhesus*, causing death of the animal, if untreated. For this reason this animal is very well adapted for testing the therapeutic activity of antimalarial remedies and has been used by the authors for this purpose for the last two years. Chopra, Mukherjee and Campbell (1933) tested the antimalarial properties of eotarnine derivatives and found their results equally applicable to plasmodium infection in man. The present authors extended

(Continued from previous column)

All the above cases were from places with no indigenous kala-azar and in each case malaria could also be ruled out. In none of them were there any signs of congenital heart disease, hereditary syphilis, rickets or tuberculosis.

Acknowledgment

It is with pleasure that I admit that the writing of this paper was prompted by my friend Dr. Radhakrishna Rao, M.B., B.S., Research Scholar of the Andhra University.

the use of this animal to chemotherapeutic studies with other drugs.

In a previous paper (1933) we have recorded the results of our investigation on the effect of atebirin on plasmodium infection in this hyper-susceptible host. It was shown that the destructive action of atebirin on this plasmodium was exceptionally powerful. Usually two doses of 0.025 gm. of the drug given intramuscularly or intravenously are sufficient to control a very heavy infection which may amount to a million parasites per c.mm. The drug equally affects both the schizogony and the gametogony, and all phases of parasites rapidly disappear from the peripheral circulation under its action. Even after a single dose, signs of degeneration are seen in the parasites and their numbers rapidly decrease (see figures 1 and 2). After two or three

Fig. 1—Blood film from a monkey showing a count of 882,000 parasites per c.mm. immediately before an injection of atebirin.

doses they disappear from the peripheral blood altogether. Owing probably to its slow excretion atebirin, when given intravenously, appears to exert a prolonged action. The drug is absorbed equally well and is effective whether given by the intravenous or intramuscular route, and there appears to be no marked difference in its action whatever mode is adopted. We have noted, however, that although the drug cures a very intense infection with marvellous rapidity, the parasites reappear in the blood between 10 and 15 days after a course of intensive treatment with large doses of the drug for 5 days. These parasites multiply in the blood with the same rapidity as in the primary attack, and cause death of the animal if prompt treatment is not given. The recrudescence can, however, be checked much more easily than the original attack. One dose of the drug as a rule suffices to control the multiplication of parasites though a low grade of infection may persist for long periods. In our series of human cases

(mostly adults), a similar relapse, within such a short period after the treatment, did not occur so frequently.

Fig. 2—Blood film of a monkey taken 22 hours after an injection of atebirin, shows that the count has come down to a negligible number and the parasites still present are all showing signs of degeneration.

In this paper we propose to give the results of our investigation regarding the effect produced by quinine on this plasmodium. Our object was to determine the relative effectiveness of quinine and atebirin on this plasmodium, and secondly to determine the comparative efficacy of the drugs given by the intramuscular and intravenous routes. The animals used in our experiments were all *Silenus rhesus* because of their ready availability and convenient size. These were infected in the usual way by subcutaneous injections of heavily parasitized blood from another monkey of the same species previously infected. The weight of the animals usually ranged between 3 to 5 kilogrammes. In most cases the treatment was commenced when the infection was heavy, the maximum being over a million parasites per cubic millimetre of blood.

In the following tables detailed observations on these animals continued for many months are recorded:

No. I, *Silenus rhesus*, 2.647 kilogrammes in weight inoculated with 0.5 c.cm. of blood containing 90,000,000 parasites (rings and schizonts). Incubation period 6 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
3-1-33	Very scanty rings.
4-1-33	10,400	..	Rings, growing trophozoites and schizonts.

No. I, *Silenus rhesus*—concl'd.

Date	Parasite count per c.mm.	Treatment	REMARKS
5-1-33	148,000	Quinine 1½ grs. i.v.	Chiefly rings.
6-1-33	174,000	Do.	Chiefly schizonts. Had convulsions immediately after the injection.
7-1-33	200,000	Do.	Very severe convulsions lasting over 15 minutes within a minute after injection.
8-1-33	178,000	Quinine 1½ grs. i.m.	Basophilia, anisocytosis and pigment-bearing mononuclears.
9-1-33	128,480	..	Chiefly degenerating trophozoites. Abnormal cells, basophiles and normoblasts.
10-1-33	Scanty	..	Degenerating.
12-1-33	15,200	..	Marked basophilia.
13-1-33	8,200
15-1-33	Scanty rings
21-1-33	Do.	..	Marked anisocytosis and basophilia.
23-1-33	Very scanty rings.
24-1-33	No parasites	..	No parasites seen in 250 microscopic fields examined.
1-2-33	Do.
18-2-33	Scanty rings	..	No abnormal cells, red cell count 4,840,000 per c.mm.
19-2-33	No parasites

The blood examined on the 27th February, 7th, 18th and 28th March, 18th April, 17th and 26th July, 10th August and 26th October showed no parasites. On the last day of examination the red cell count was 5,120,000 per c.mm.

Quinine in doses of 1½ grains intravenously produced convulsions and appears to be too large for a monkey weighing 2½ kilogrammes. As the daily dose of 1½ grains intravenously produced practically no effect on the parasite count, an intramuscular injection of the same dose was given, after which the count came down gradually. A low grade of infection, however, persisted for about 40 days. After that period parasites had not been detected in smears examined on 10 occasions, the last being done on 26th October, 1933. This monkey was under observation for more than 10 months.

No. II, *Silenus rhesus*, 3.46 kilogrammes in weight, inoculated with 0.2 c.cm. of blood containing 110,800,000 parasites (rings and schizonts). Incubation period 13 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
6-2-33	85,000	Quinine 1½ grs. i.v.	Schizonts and a few gametocytes.
7-2-33	68,480	Do.	..
8-2-33	12,400	Do.	..
9-2-33	Scanty	Do.	Growing trophozoites.
10-2-33	+ (no count)	..	Do.
11-2-33	Do.	..	Do.
13-2-33	Do.	..	Do.
14-2-33	Scanty
18-2-33	+ (no count)
20-2-33	Do.
21-2-33	Very scanty	..	Schizonts.
22-2-33	No parasites

Examinations made on the 27th February, 7th, 18th and 28th March, 18th and 21st April, 17th July, 10th August and 26th October showed no parasites.

In this animal the treatment was started when the count was not high, i.e., less than 100,000 parasites per c.mm. After the treatment, the count showed a slow and gradual decrease, and the animal had no relapse and apparently recovered. This monkey was under observation for more than 9 months.

No. III, *Silenus rhesus*, 4.155 kilogrammes in weight, inoculated with 0.5 c.cm. of blood containing 62,000,000 parasites (all rings). Incubation period 8 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
13-3-33	++ (no count)	..	Rings and schizonts.
14-3-33	348,000	Quinine 1½ grs. i.v.	Chiefly rings.
15-3-33	680,000	Do.	..
16-3-33	700,000	Do.	..
17-3-33	1,036,000	Do.	..
18-3-33	46 per cent r.b.c.'s infected.	..	Extremely anæmic; monkey died at night.

In this animal treatment was started when the count was fairly high. In spite of the daily intravenous injection of the maximum doses of quinine, the parasites went on increasing in number and ultimately killed the animal.

No. IV, *Silenus rhesus*, 3.825 kilogrammes in weight. Incubation period 8 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
1-5-33	6,820	Quinine 1½ grs. i.v.	Rings and schizonts. Severe convulsions within 5 minutes after the injection.
2-5-33	80,280	Quinine 1 gr. i.v.	..
3-5-33	46,200	Do.	..

No. IV, *Silenus rhesus*—concl'd.

Date	Parasite count per c.mm.	Treatment	REMARKS
6-5-33	No parasites	Quinine 1 gr. i.v.	..
10-5-33	Do.
29-5-33	+ (no count)
17-7-33	Do.
26-7-33	Scanty parasites.	..	Rings.
14-8-33	No parasites
15-8-33	Do.
17-8-33	Died of pneumonin.

Post-mortem examination showed consolidation of large areas of both the lungs. No parasites were detected in the heart blood.

In this animal, treatment was started on the very day the parasites were first detected in the blood smear. Though the count showed no increase in the number of parasites for a couple of days, it came down gradually and eventually the parasites disappeared altogether.

No. V, *Silenus rhesus*, 4.1 kilogrammes in weight, inoculated with 0.25 c.cm. of blood containing 17,060,000 parasites. Incubation period 4 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
22-5-33	++ (no count)	..	Growing trophozoites and schizonts.
23-5-33	420,000	Quinine 1½ grs. i.v.	..
24-5-33	820,000	Do. (11-30 A.M.)	..
		Do. (3 P.M.)	..
25-5-33	1,100,000	Do. (1 P.M.)	..
		Do. (4-20 P.M.)	..
26-5-33	28,280	..	Degenerated growing trophozoites.
29-5-33	Scanty	Quinine 1½ grs. i.v. (4-20 P.M.)	Basophilia and normoblasts.
30-5-33	+ (no count)	Do.	Pigmented leucocytes.
1-6-33	Do.
2-6-33	++ (no count).	..	Schizonts, Normoblasts, basophiles and pigmented leucocytes.
7-6-33	Scanty	..	Schizonts.
8-6-33	+ (no count).	..	Gametocytes.
13-6-33	No parasites
21-6-33	Do.	..	A few pigmented leucocytes.
23-6-33	Scanty	..	Schizonts.
24-6-33	Do.	..	Trophozoites and schizonts.
17-7-33	No parasites

Examinations were made on the 26th July, 10th and 18th August, 19th September, and 26th October with negative results. The red cell count on the last day of examination was 5,650,000 per c.mm.

In this animal 24 hours after the first injection of quinine the count was graded. As one dose intravenously per day was effective in reducing the

number of parasites, it was decided to give two injections at an interval of 3½ hours so as to ensure the presence of quinine in the blood for longer periods. The injections were repeated at the same interval on the following day also. The parasite counts came down and the monkey gradually recovered.

A monkey of 4 kilogrammes in weight cannot stand a dose of over 1½ grains, given intravenously, but the same dose can be safely repeated after 3½ hours. Intravenous administration of quinine twice a day appears to be effective in eradicating even a heavy infection. This monkey was under observation for over six months.

No. VI, *Silenus rhesus*, 4.565 kilogrammes in weight, inoculated with 0.5 c.cm. of blood containing 80,000,000 parasites. Incubation period 4 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
13-10-33	Scanty
14-10-33	+++ (no count)
16-10-33	1,240,000	Quinine 1½ grs. i.v.	..
17-10-33	1,880,000	Do.	..
18-10-33	Died at night. Heart blood full of parasites.

No. VII, *Silenus rhesus*. This monkey weighing 4.5 kilogrammes was infected 4 times during the period from August 1931 to 25th November, 1932, and treated with small doses of quinine from time to time to produce a condition of chronicity of infection. On 7th August, 1933, the monkey was inoculated for the fifth time with 0.5 c.cm. of blood containing 29,140,000 parasites, without any response. On 30th August, 1933, another injection was given of 1.5 c.cm. of blood containing 29,140,000 parasites, but this also gave negative results. It may be mentioned that one-sixth of this dose is sufficient to produce infection under normal conditions.

On 14th October, 1933, a still bigger dose, amounting to 2 c.cm. of blood from a heavily infected animal, was given. After an incubation period of 11 days the parasites appeared but the rate of multiplication was definitely slow as compared with a monkey with primary infection. This monkey was under observation for more than two years.

Date	Parasite count per c.mm.	Treatment	REMARKS
26-10-33	Scanty	..	Rings.

19-9-33	Do.
26-10-33	Do.	..	Red cell count 5,120,000 per c.mm.

In this animal, parasites were not very numerous when the treatment was commenced. The count came down to nearly a third of the original number 24 hours after the first injection and no parasites could be found after two injections. But they appeared in scanty numbers from time to time for about two months. Since that time the blood has been negative on 5 monthly examinations.

On the 26th October, 1933, when the monkey was examined last, it looked quite healthy showing a total r.b.c. count of 5,128,000 per c.mm. This monkey was under observation for more than seven months.

No. IX, *Silenus rhesus*, 3.580 kilogrammes in weight, inoculated with 0.5 c.cm. of blood containing 42,140,000 parasites. Incubation period 7 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
22-3-33	A few	..	Rings.
23-3-33	564,000	Quinine 1½ grs. i.m.	Rings and schizonts.
24-3-33	590,400	Quinine grs. ii, i.m.	Chiefly growing trophozoites.
25-3-33	Very scanty	Do.	Degenerating. Pigmented leucocytes present.
26-3-33	Scanty	Do.	Degenerating.

Date	Parasite count per c.mm.	Treatment	REMARKS
11-4-33	No parasites
18-4-33	Scanty	..	Schizonts.
21-4-33	No parasites
27-4-33	Do.
1-5-33	Do.
5-5-33	Do.
16-5-33	+ (no count).	..	Growing trophozoites.
18-5-33	+ (no count).	..	Do.
19-5-33	No parasites	..	Basophilia present.
17-7-33	Do.
18-8-33	Do.
26-10-33	Do.

In this animal a slight increase of the count was noticed after the first injection, but 24 hours after the second injection the count was negligible and the parasites were mostly degenerating. Scanty infection persisted for about two months; after that period the animal appeared to be free. The last examination of blood was made about 4 months after the last appearance of the parasites. This animal was under observation for more than seven months.

No. X, *Silenus rhesus*, 3.490 kilogrammes in weight, inoculated with 0.5 c.cm. of blood from a heavily infected monkey. Incubation period 6 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
3-4-33	+ (no count)	..	Rings and schizonts.
4-4-33	1,742,000	Quinine grs. ii, i.m.	Chiefly rings.
5-4-33	1,296,000	Do.	Growing trophozoites.
6-4-33	401,200	Do.	..
7-4-33	Scanty	..	Degenerating, basophiles and normoblasts, etc.
8-4-33	No parasites
9-4-33	Do.
17-4-33	Died. Post-mortem examination showed innumerable parasites in the heart blood.

In this animal parasites apparently disappeared after a course of 4 injections, but they reappeared and multiplied with great rapidity and killed the animal 10 days after the last dose. Here quinine behaved like atabrin in its action on the monkey plasmodium.

No. XI, *Silenus rhesus*, 5.4 kilogrammes in weight, inoculated with 0.4 c.cm. of blood from a very heavily infected monkey. Incubation period 8 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
5-7-33	++ (no count).	..	Rings, growing trophozoites, and schizonts.
6-7-33	++ (no count).	..	Rings and schizonts.

No. XI, *Silenus rhesus*—concd.

Date	Parasite count per c.mm.	Treatment	REMARKS
8-7-33	+++ (no count).	..	Rings, growing trophozoites and schizonts.
9-7-33	52,240	Quinine grs. ii, i.m.	Do.
10-7-33	48,620	Do.	Trophozoites mostly degenerating.
11-7-33	No parasites	Do.	..
12-7-33	Do.	Do.	Marked anisocytosis.

Blood examined on the 13th, 17th and 26th July, 10th and 26th August, 10th and 19th September and 26th October showed no parasites.

Treatment was started fairly early. After a course of 4 injections the parasites disappeared altogether, and were never found during a period of three months.

No. XII, *Silenus rhesus*, 3 kilogrammes in weight, inoculated with 0.5 c.cm. of heavily infected blood. Incubation period 4 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
13-7-33	605,000	Quinine grs. ii, i.m.	Chiefly rings (see figure 3).
14-7-33	1,500,000	Do.	Rings and schizonts.
15-7-33	1,644,000	Do.	..
17-7-33	25,200	Do.	Trophozoites degenerating.
18-7-33	Very scanty	Do.	Very marked basophilia, normoblasts and marked anisocytosis.
22-7-33	No parasites
26-7-33	Do.
10-8-33	Very scanty	..	Rings.
16-8-33	No parasites
2-10-33	Do.
23-10-33	Scanty	..	Rings.
26-10-33	No parasites

Fig. 3.—Blood film of monkey XII taken immediately before quinine was administered, showing a count of 605,000 parasites per c.mm.

Parasites continued to increase in number even after 2 injections (see figure 4), but were scanty after four injections. Low grade of infection, however, persisted for three months.

Fig. 4.—Blood film of monkey XII taken 24 hours after an injection of quinine showing an increase in the number of parasites and diminution of red cells. Parasites 1,500,000 per c.mm. Red cells 2,100,000 " "

Four months after the completion of treatment the monkey developed a severe relapse and died. Smears of heart blood showed an infection of very severe intensity, nearly 80 per cent of red cells being infected.

No. XIII, *Silenus rhesus*, 3 kilogrammes in weight, inoculated with 0.4 c.cm. of blood containing 82,000,000 parasites (chiefly rings). Incubation period 5 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
19-7-33	Very scanty
20-7-33	+ (no count).	..	Rings.
21-7-33	300,480	..	Chiefly rings.
22-7-33	2,016,000	Quinine grs. ii, i.m.	Rings, schizonts and a few gametocytes.
23-7-33	1,203,200	Do.	Chiefly schizonts, r.b.c. 3,760,000 per c.mm.
24-7-33	98,600	Do.	Chiefly trophozoites, r.b.c. 3,280,000.
25-7-33	6,960	Do.	Trophozoites. Anisocytosis, basophilia and demilune cells, r.b.c. 3,280,000.
26-7-33	No parasites	Do.	R.b.c. 3,580,000.
10-8-33	Do.	..	R.b.c. 5,620,000.
2-10-33	Do.
26-10-33	Do.

In this animal injection was started when the count was exceptionally high, more than 50 per cent of r.b.c. being parasitized. Parasites disappeared after the fourth injection. The animal was under observation

for about three months after the course of treatment during which period occasional examinations of its blood were made, but no parasites could be detected.

No. XIV, *Silenus rhesus*, 4,320 kilogrammes, inoculated with 0.25 c.cm. of blood containing 75,120,000 parasites (rings only). Incubation period 4 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
26-7-33	+	..	Rings, r.b.c. 5,610,000 per c.mm.
27-7-33	17,280	..	R.b.c. 4,820,000 per c.mm.
28-7-33	774,400	Quinino grs. ii, i.m.	R.b.c. 4,840,000 per c.mm.
29-7-33	921,600	Do.	R.b.c. 3,560,000 per c.mm.
30-7-33	24,000	Do.	Parasites degenerating, r.b.c. 2,000,000 per c.mm.
31-7-33	Very scanty	Do.	Marked anisocytosis, basophilia, achromia and normoblasts, r.b.c. 2,200,000 per c.mm.
1-8-33	No parasites	..	R.b.c. 2,320,000 per c.mm.
10-8-33	Scanty	..	Rings, r.b.c. 5,840,000 per c.mm.
16-8-33	+	..	Schizonts and gametocytes.
28-8-33	Scanty	..	Rings.
17-9-33	No parasites
26-10-33	+	..	Schizonts.

After the first injection the count showed a little increase, but after two injections it came down considerably. A low grade of infection persisted for nearly three months.

No. XV, *Silenus rhesus*, 4,689 kilogrammes in weight, inoculated with 0.5 c.cm. of blood containing 103,600,000 parasites (chiefly mature schizonts). Incubation period 8 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
9-9-33	Scanty	..	Rings and schizonts, r.b.c. 5,640,000.
11-9-33	800,000	Quinine grs. ii, i.m.	Rings and schizonts, r.b.c. 4,000,000.
12-9-33	72 per cent r.b.c. infected.	Do.	R.b.c. 1,120,000.
13-9-33	Monkey died.

This animal showed a hyper-susceptibility to the infection. In spite of a full dose of quinine given intramuscularly, the count went up from 800,000 to 2,880,000 per c.mm.—a condition hardly compatible with life.

No. XVI, *Silenus rhesus*, 4,630 kilogrammes in weight, inoculated with 1 c.cm. of blood containing 800,000,000 parasites (schizonts and rings). Incubation period 4 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
16-9-33	10.2 per cent cells infected.	Quinine grs. iii, i.m.	Chiefly rings, r.b.c. 5,840,000.
17-9-33	18.5 per cent cells infected.	Do.	All schizonts, r.b.c. 4,460,000.
18-9-33	42.1 per cent cells infected.	Do.	R.b.c. 3,280,000. Animal very ill.
19-9-33	19.9 per cent cells infected.	..	R.b.c. 2,480,000.
20-9-33	0.3 per cent cells infected.
25-9-33	No parasites
2-10-33	+++ (no count)	Quinine grs. iii, i.m.	Rings, growing trophozoites and schizonts.
3-10-33	+	Do.	Rings and schizonts.
5-10-33	No parasites
9-10-33	Do.	..	Died. Post-mortem examination next day showed innumerable parasites in the heart blood.

To ascertain if larger doses of quinine would produce a quicker effect on the parasite count this animal was given a dose of grs. 3 per diem. The site of the inoculation was so much inflamed that we had to stop the injections for a time after the third. Two more injections were however given after the inflammation had subsided.

It will be seen that the effect of large doses was far less than with smaller doses. This is probably due to the damage of the tissue caused by large doses and consequent interference with proper absorption of the drug.

Discussion

A perusal of the tables will show that in monkeys I to VI quinine was administered intravenously, while in monkeys VII to XVI it was given by the intramuscular route.

Dosage.—Monkeys weighing between 3 and 4 kilogrammes can stand a dose of $1\frac{1}{2}$ grains of quinine intravenously, if administered very slowly, but a larger dose, 2 grains, usually causes death of the animal. Even with a dose of $1\frac{1}{2}$ grains the animal may get convulsions immediately after the injection which may not be fatal (monkeys I and IV). By the intramuscular route 2 grains dissolved in 1.5 c.cm. of water can be given without any untoward symptoms. A dose of 3 grains, however, dissolved in the same amount of water produces inflammation of the part injected which is so severe that it becomes difficult to give a second injection in the same area for many days. The last-mentioned dose is not only irritating to the tissues, but is also far less effective than

a two-grain dose, probably owing to the drug not being properly absorbed from the damaged tissues (monkey XVI). The number of injections given were 3 to 5, as compared with five days' treatment with atebtrin.

Intravenous series.—In our previous paper (1933) we have recorded that on this plasmodium atebtrin has an almost equally effective action whether it is given by the intravenous or by the intramuscular route. The state of affairs is somewhat different with quinine. After one intravenous or intramuscular injection of atebtrin the number of parasites in the peripheral blood showed a remarkable fall; in the case of quinine the parasites showed a distinct increase after the first and the second injection; this is clearly brought out throughout the intravenous series (monkeys I to VI). We attributed this to a more rapid excretion of quinine when given by the intravenous route so that the contact of the drug with the parasites is of shorter duration than in the case of atebtrin. In monkey V, therefore, in order to maintain contact for a longer period, two intravenous injections of quinine at an interval of about 3 to 4 hours were given; even after this the parasites in the peripheral circulation steadily increased in number. It was on the third day of administration that there was a definite and remarkable decrease in their number. In the case of atebtrin, one injection whether intravenous or intramuscular brought down the parasites to a negligible amount. These experiments clearly indicate that quinine administered by the intravenous route has a decidedly slower action on this plasmodium than atebtrin, and after the administration of the drug is started, sufficient time may elapse to allow the parasites to multiply and produce death of the animal (monkeys III and VI). In fact it would appear that the first intravenous injection of quinine in these animals not only was ineffective in stopping parasite multiplication but actually stimulated it. In plasmodium infection in man we have also observed a similar increase in the number of parasites after an intravenous injection of quinine (Chopra *et al.*, 1932).

A study of tables I to VI will show that unless the injections are started fairly early in the infection, administration of quinine by this route is ineffective. If, however, the intravenous injections are repeated at short intervals, say of 4 or 5 hours, even a heavy infection, *i.e.*, about half a million per c.mm., can be controlled (monkey V).

Intramuscular series.—We have already referred to the marvellous effect produced by intramuscular injections of atebtrin on this plasmodium. The parasites circulating in the peripheral blood are rapidly destroyed after one injection, their number shows a considerable decrease and degeneration sets in in the body of the parasite almost immediately. If quinine is administered when the parasite count is low

(monkeys VIII and XI) the infection can be quickly brought under control after one injection, but if the count is about half a million or more (monkeys IX, X, XII, XIII and XIV) two or three intramuscular injections are necessary to get the infection under control. The intramuscular injections of quinine, like the intravenous injections, appear to have a more gradual action on the parasites and there is as a rule no remarkable decrease in their numbers for 24 hours after injection or even longer.

Comparative effects of atebtrin and quinine

A careful study of the action of atebtrin and quinine on this plasmodium shows that atebtrin has a much more powerful immediate effect on the parasites than quinine. Even when the parasite count in the peripheral blood is high, *i.e.*, about half a million per c.mm., one dose of atebtrin brings down the number and controls the infection. In the case of quinine one dose, intramuscular or intravenous, is only effective when the parasite count is low, *i.e.*, below 100,000 per c.mm. When the count is high, *i.e.*, above half a million, 2 or 3 injections are necessary to control the infection. The difference, however, in the remote effects of the two drugs on the infection is remarkable, so far as the reappearance of parasites in the blood and the virulence of the relapse is concerned; whereas after 5 days' intensive treatment with atebtrin in large doses, the parasites invariably reappeared in 10 to 15 days and multiplied with the same rapidity as in the primary attack, causing death of the animal if prompt treatment were not given, in the case of quinine often the parasites did not reappear in the blood (monkeys XI and XIII) and if they did appear (monkeys VIII, IX, XII and XIV) they were scanty in number, did not multiply and did not produce death of the animal. In this relapse the parasites often disappeared spontaneously without treatment, or a very low grade of infection persisted, as was the case in the atebtrin series, only after the treatment of the relapse with the drug. In only two animals (monkeys X and XII) was death produced after relapse, whereas after a full course of atebtrin the first relapse, if untreated, was practically always fatal.

The conclusion which can be drawn from these observations is that, although the immediate effect of quinine on the plasmodium infection is not so remarkable as atebtrin, this alkaloid has a more lasting action and has a stronger effect in eradicating the infection, so that either the parasites disappear from the peripheral blood altogether or if they reappear they cannot multiply rapidly (as after atebtrin) and produce death of the animal. It may be pointed out here, that treatment with atebtrin increases the susceptibility of the parasite to the action of this drug, as with one dose of the drug a very severe relapse that would otherwise end fatally can be successfully treated and the infection controlled.

So far as the relative efficacy of intravenous and intramuscular injections of quinine on this plasmodium is concerned, it is evident from these experiments that there is not much to choose. If anything, the effect of the former would appear to be less powerful and less lasting than of the latter. Two factors are concerned in the destructive action of the drug on the parasites, i.e., firstly concentration of the drug and, secondly, its duration of contact. So far as the concentration is concerned, an intravenous injection must produce, for the time being at any rate, a higher concentration in the peripheral blood than an intramuscular injection; the quinine given by this route, however, is very rapidly excreted so that the maintenance of this concentration is probably of much shorter duration than in the case of the intramuscular route, in which a constant supply of the drug is maintained for some time from the site of injection; the contact is therefore longer following intramuscular injections than following intravenous, and this may account for the great efficacy of the former. Acton and Chopra (1924) showed that quinine can be detected at the site of injection for at least 24 hours after injection.

These experiments bear out the contention of Acton and Chopra (1927) that very small concentrations of quinine may stimulate the growth of the plasmodium.

Possibility of the development of resistance or immunity to infection

During the course of acute infection the number of red blood corpuscles fell from about $5\frac{1}{2}$ millions per c.mm. (normal count) to about two millions or even less. But it is surprising that the animal regains its normal count in about 10 days after a course of treatment.

The question of immunity produced in malaria has been discussed largely in the literature of late years and the evidence is gradually accumulating in favour of its production. In this connection the case of monkey VII is worth notice. This animal was under observation for over two years after his first infection with the plasmodium from which he was saved by treatment with quinine. Since then it has been given very large doses of the plasmodium; on the first two occasions it failed to take the infection at all, but on the third the parasites appeared after a delayed incubation period and the rate of multiplication was markedly slow as compared with a monkey with a primary infection.

Summary

It is fully realized that the series of animals on which these observations have been made is very small, but as the monkeys have to be kept under observation for many months and the examinations are laborious the difficulty of

doing a larger series can be understood. It is not, therefore, claimed that the results obtained are of universal application but they help in understanding the effect produced by these drugs on this plasmodium. This paper is a continuation of our previous paper (1933) and should be read along with it.

Our observations show that the action of quinine on this plasmodium is slower than that of atebirin. If the treatment is started at the time when the infection is moderately heavy, the parasite count does not seem to be affected in most cases for 24 hours or even longer with quinine whereas with atebirin, even if the treatment is started late, i.e., when the count exceeds half a million parasites per c.mm., this invariably falls to a negligible number (see figures 1 and 2). After a 3 or 4 days' course of treatment with quinine, a low grade of infection may persist even up to a period of 3 months and after that period it usually dies out. But rarely a monkey may suddenly show a very rapid multiplication of the parasite followed by death of the animal if left untreated. On the other hand after a full course of atebirin the parasites disappear from the peripheral circulation for 10 or 15 days and after this period reappear and multiply with very great rapidity, so much so that the animal dies in two or three days if treatment is not started immediately. The parasites appearing during the relapse are very susceptible to the action of atebirin and one dose suffices to control the infection.

The intramuscular injections of quinine appear to be somewhat more efficacious than intravenous and their effect seems to be more lasting. Some evidence has also been produced to show that resistance or immunity is produced against this infection in monkeys.

THE PLACE OF TREATMENT IN AN ANTIMALARIAL CAMPAIGN

By W. B. McQUEEN, M.B., Ch.B. (Glasgow)
D.T.M. (Liverpool)

INTRODUCTION

THE practice with which this paper deals is situated in Upper Assam, near the North Eastern Frontier, and comprises ten tea gardens owned by five companies, one company having five gardens, one company two, and three companies one each. The district is bisected by a river, and the areas occupied by the gardens abound in river-flood plains, in broad and narrow plains on which rice is grown in the

From November to April the minimum temperature is below 65°F. and few infected mosquitoes are found. During May conditions are very variable. It may be a hot dry month—maximum temperatures of 102°F. have been recorded—or there may be a fairly high rainfall as during 1932.

The rains or monsoon season commences about mid-June, and from this time until mid-October, the maximum and minimum temperatures are practically constant. The absolute and relative humidities are both high, as the average rainfall is in the neighbourhood of 20 inches monthly.

The following table gives the temperatures, etc., for 1932 :—

TABLE I

Month			TEMPERATURE		HUMIDITY				Rainfall inches
			Max.	Min.	Relative		Absolute		
					9 A.M.	3 P.M.	9 A.M.	3 P.M.	
January	70.9	50.3	89.13	59.65	4.59	4.67	2.17
February	71.8	50.5	81.87	52.10	4.41	4.20	2.62
March	80.1	57.8	77.08	51.73	5.41	5.39	4.64
April	84.5	64.1	72.54	52.95	6.42	6.33	5.08
May	82.1	69.7	84.97*	73.37*	7.74*	8.12	16.82*
June	87.3	75.0	88.31	75.78	9.47	9.12	24.27
July	90.8	75.9	82.32†	66.87†	9.47	9.81	19.37
August	87.7	75.9	87.69	72.03	9.37	9.68	18.84
September	87.1	74.6	86.39	70.77	9.24	9.81	19.28
October	84.2	69.2	82.94	67.82	7.98	8.01	3.53
November	78.2	61.8	89.37	69.20	6.75	6.94	3.84
December	71.7	52.0	88.66	64.91	4.91	5.42	1.99

Note.—Relative humidity given in percentages.

Absolute humidity given in grains per cubic foot.

* Abnormally high.

† Abnormally low.

In 1932 May was an abnormally wet month, the rainfall being the highest for at any rate 12 years.

rains when they are flooded, and in water channels of various kinds, some dry in the cold weather and some containing water throughout the year. In some places undrained swamps are still to be found.

The climate is sub-tropical, and there are two main seasons, a cold dry one, and a hot wet one. The former is characterized by a greater daily range of maximum and minimum temperatures, by considerably lower rainfall, and consequently lower humidity, both relative and absolute. The latter is characterized by smaller daily range of maximum and minimum temperatures, by high rainfall and consequently higher average humidity.

The area was surveyed by a malarialogist during 1924, and an antimalarial officer, experienced in antilarval methods, was left by him to supervise the carrying out of the recommendations made, which he has continued to do until now.

As regards treatment, from 1924 till 1930 all cases of 'fever' were admitted to hospital, and when the diagnosis of malaria was made, the fever was controlled as quickly as possible by the administration of quinine, and when the temperature had remained normal for a few days, the patient was discharged to a 'challan' on which for three months adults received ten grains of quinine in liquid form daily, and

children according to age. During 1925 all children of seven years and under received a daily dose of equinine in milk, but this was done during one year only.

In 1930, when I took charge of the practice, considerable dissatisfaction was being expressed at the lack of results from the enormous expenditure on antimalarial work. Although the spleen rates had been slightly lowered, the companies naturally had been expecting a very obvious improvement in the health of the labour forces, as shown in admissions to hospitals for malaria, and in the death rates.

During that year, 1930, no changes in treatment were made except the limiting of injections of quinine to cases where injection was definitely indicated.

Auxiliary methods.—In 1931 the standard treatment of malaria recommended by Sinton (1930)* was introduced throughout the practice, and all children with enlarged spleens were given quinoplasmochin twice weekly during June, July, and August. Owing to the lack of a laboratory staff, it was impossible to estimate the parasite rate on any garden, but it was considered reasonable to presume that the percentage of gametocyte carriers was high, and that the larger the number of people treated the better. Consequently we encouraged admissions for malaria, and also gave the treatment to many who had enlarged spleens, but who had come to hospital for reasons other than malaria.

The most important class under this heading was anæmia, secondary in type. For many years anæmia had been so prevalent that the hospital accommodation had been quite inadequate for indoor treatment, and the system adopted was to put all those found with an hæmoglobin index of 50 per cent or under on light work. Those with 40 per cent or less were given a meal in the morning, a dose of iron tonic, and one-third work with full pay. Those with 45 per cent to 50 per cent hæmoglobin were given a meal, a dose of quinine, iron and arsenic tonic, and two-thirds work with full pay. All were treated for hookworm regularly, and progress in most cases was slow.

During 1931 we admitted as many of these cases as possible to hospital for a 'Sinton' treatment, and the result in many cases was wonderful. The hæmoglobin index rose steadily, and it was possible to discharge many to full work immediately the course was finished. In others a subsequent short course of iron tonic treatment was necessary.

The standard treatment was not popular with the labour forces or with the managers, chiefly because of the length of stay in hospital required. Accordingly this was changed in 1932 to the treatment recommended by Knowles (1931)†, and, as an experiment, all the children in one

line per garden were given plasmochin once daily for six days each alternate week for six months.

Results.—The following diagrams show the results up to 1930 and for 1931 and 1932. Group A represents the company with five gardens, and Group B the five gardens owned by the other four companies.

* This consists of 210 grains of quinine, preceded by alkalis, and 0.105 gramme of plasmochin, spread over a period of a week.—EDITOR, I.M.G.

† This consists of 200 grains of quinine, preceded by alkalis, and 0.06 gramme of plasmochin, spread over a period of 10 days, the plasmochin being given in daily doses of 0.01 gramme during the last six days.—EDITOR, I.M.G.

At little more than a glance one can see that the position in 1930 as regards admissions was worse than in 1925, and as regards deaths very little better.

During 1932 we reaped the benefit of the work done in 1931. In group A the malarial incidence was less than for any of the other years shown, and the death rate from all causes was also less. In group B the incidence was the lowest since 1925, the death rate being much the same as in other years.

Results of plasmochin treatment of children

In the lines chosen for giving plasmochin to the children there had been a high malarial incidence previously. In the population of the five lines in group A the malarial incidence had been 170 per mille in 1930, and 190 per mille in 1931. In 1932 it was 104 per mille.

In group B the incidence had been 293 per mille in 1930, and 323 per mille in 1931. In 1932 it was 200 per mille.

Re-treatments

A certain percentage of patients who have been treated once had to undergo a second course of treatment. These percentages are given below:—

TABLE II

	Group A	Group B
1931	10.92	32.78*
1932	13.63	24.96

* One garden in this group had to give up curative treatment in the rains, on account of lack of hospital accommodation.

Many of these may have been reinfections as *Anopheles minimus*, the carrier here, were caught in large numbers, not as an antimalarial measure, but for dissection: one insect collector on each garden was employed for this purpose.

The mosquito catches are given below:—

TABLE III

	Group A	Group B
1931	5,500	9,696
1932	5,230	7,968

TABLE IV

Mosquito (*A. minimus*) dissections

	Number dissected.	Number infected.	Per cent infected.
1929 September—December	879	17	1.9
1930 May—November	549	13	2.4
1931 May—November	1,239	45	3.6

Total admissions to hospital

In this connection, an important factor other than malaria must be mentioned. Steam-milled rice, deficient in vitamin B complex has been gaining popularity steadily with the labour forces, and only at the beginning of 1933 was sufficient interest aroused for attention to be given to this important factor in predisposing to disease.

TABLE V

	Total admissions per mille	
	Group A	Group B
1930	400	514
1931	425	588
1932	367	489

To keep the labour forces up to strength, considerable recruiting is necessary every year. Had any change been made in 1932, for instance had more so-called 'immunes' to malaria been imported that year, it might have been said that therein lay the reason for the improvement. But no change was made.

Conclusion.—No doubt the ideal solution of the malaria problem in Assam would be the elimination of the carrier mosquito, but until effective practical measures are devised, and prove effective, it appears that here, where conditions are ideal for the breeding of *A. minimus*, and for the development of the parasite in the mosquito, auxiliary antigametocyte measures are essential for the achievement of even a limited success.

I am indebted to the Directors for permission to publish this article and to the scientific department of the companies for the table of temperatures, humidity and rainfall.

REFERENCES

Knowles, R. (1931). Clinical Studies in Malaria by cultural and enumerative methods. *Indian Med. Gaz.*, Vol. LXVI, p. 1.

Sinton, J. A. (1930). A Suggested Standard Treatment of Malaria based upon the results of the controlled investigation of over 37,000 cases. *Indian Med. Gaz.*, Vol. LXV, p. 603.

[Note.—We do not believe that the writer meant to criticize antilarval measures in general. There can be no possible doubt that in many places in Assam these measures have been very successful in controlling malaria, in others heavy expenditure has produced little immediate effect. The gardens referred to in this paper appear to fall into the latter category. It seems probable that in these circumstances effective treatment and antigametocyte measures will be necessary to supplement, rather than to replace, the antilarval measures.

In the gardens of group A, the mean of the malarial incidence for the seven years, 1925 to 1931, was 142 and the standard deviation of these seven experiences ± 17 . The figure for 1932 was 91, with a standard deviation ($\sqrt{N.P.Q.}$) of $\sqrt{82.719}$. The standard deviation of the difference of these two figures is therefore $\sqrt{289 + 83}$ or ± 19.3 . Therefore the difference between the mean malarial incidence of the previous seven years and that for 1932, namely $142 - 91 = 51$, is definitely significant, if the methods of collecting the figures were strictly comparable.

NINE CASES OF HUMAN GNATHOSTOMIASIS

By CHALERM PROMMAS, D.F.H.

and

SVASTI DAENGSVANG, D.F.H. (Johns Hopkins)
D.T.M. (Cal.)

(From the Department of Pathology, Faculty of Medicine, Chulalongkorn University, Bangkok, Siam)

Up to the present twelve cases of human gnathostome infestation have been recorded in the literature from various eastern countries. During the past few years we have collected nine cases in Bangkok; seven cases have already been mentioned by Prommas and Daengsvang (1933), and two further cases are now added.

Case 1.—Nang P., female, Siamese, store-keeper and housewife, resident of Bangkok, *et. 31*, who was fond of petting cats and did not eat raw meat and vegetables. Family and past histories were not significant. About 6 or 7 years ago she suffered from migrating swellings which appeared on her arms and legs; these were accompanied by slight itching and boring pain, and sometimes by redness. They appeared at variable intervals of weeks or months, varied in size, and frequently subsided after application of tincture of iodine but they usually disappeared spontaneously. The last swelling occurred on the anterior abdominal wall; from this a worm was extracted and she has been free from the condition since.

Parasite.—The worm after fixation measures 9.36 mm. in length and 0.77 mm. in width. The anterior extremity is provided with a pair of trilobate lips and a cephalic bulb which measures 0.25 mm. long and 0.77 mm. wide and is furnished with eight rows of single-pointed spines pointing posteriorly. The eighth row is not yet fully developed. The anterior two-thirds of the body is covered with spines which are broad, tridentate and dense near the broad end that becomes single-pointed and sparse as one proceeds posteriorly. The posterior third of the body is without spines. The posterior extremity forms two cuticular expansions or alæ each supported by four large papillæ. There are two unequal simple spicules. The alimentary system consists of a muscular œsophagus and an intestine. The latter is full of blood and opens into a subterminal anus. There are two pairs of cervical sacs, one on each side of the œsophagus, and are about one-sixth of the body length. The parasite is apparently a nearly full grown male *G. spinigerum*, shrunk to a certain extent after fixation.

Case 2.—Nai Ch., male, Siamese student, resident of Bangkok, *et. 22*, who was very fond of domestic animals, especially dogs and cats, and had the habit of eating raw meat and vegetables. Family and past histories were not important. In October 1929 he

developed a swelling on the right side of his face with slight irritation but without signs of inflammation or fever and he was seen by Professor T. P. Noble, head of the Surgical Department. The swelling persisted till

Fig. 1.—Photomicrograph of the head of the parasite in case 2 showing lips, cephalic bulb with eight rows of spines and anterior part of the body thickly covered with spines.

Fig. 2.—Photomicrograph of the tail of the parasite in case 2 illustrating alæ of its posterior extremity.

(Continued from previous page)

However, in group B, the mean of the malarial incidence for the seven years, 1925 to 1931, was 194 and the standard deviation of these seven experiences ± 25 . The figure for 1932 was $170 \pm \sqrt{141}$. The standard deviation of the difference between this figure and the mean is therefore $\sqrt{625 + 141}$ or ± 27.7 . The difference therefore between the malarial incidence of the previous seven years and of 1932 is not significant.

On the other hand if we take into consideration only the cooler lines in which plasmochin treatment of children was given—although the figures are of less value, because the populations are not indicated and the malarial incidences are available for only two years—the figures, such as they are, do suggest a significant improvement in the malarial state of both these sets of lines during 1932.—Error, I.M.G.]

the sixth day on which he felt something penetrating the inner side of the right cheek, and from this place a worm was extracted with a dissecting needle by a friend. After extraction of the worm the swelling gradually disappeared.

Parasite.—The worm is identified as a male *G. spinigerum* which measures after fixation 6.80 mm. long and 0.51 mm. wide. The cephalic bulb is 0.20 mm. long and 0.37 mm. wide and furnished with eight rows of fully-developed single-pointed spines. Its general morphology is identical with that of the worm in case 1, but in addition sets of fine spines are definitely seen on the inner side of the caudal alae.

Case 3.—Nang Ch., female, Siamese, a housewife, resident of Bangkok, *æt.* 34, who was fond of petting cats and gave no history of taking raw food. Family and past histories negative. She had suffered from a creeping swelling for about three years, which varied in size and position, was occasionally accompanied by very severe boring or biting pain and inflammatory symptoms lasting for two or three days. The parts of the body most frequently affected were her arms, legs and abdomen. At each attack there were no more than two swellings. She had been treated with various kinds of native drugs without effect. On 21st June, a tumour, with a severe pain boring or biting in character, about 7.5 cm. in diameter, occurred on the left iliac region. At the centre a minute black spot was observed about the size of a pin-head surrounded by a small red area. It was thought to be an abscess and was pricked with a needle by her husband; a small amount of serous fluid and a living worm were expressed. On the next day the swelling rapidly subsided.

Parasite.—It is a male *G. spinigerum* measuring after fixation 7.20 mm. in length and 0.43 mm. in width. The cephalic bulb is 0.19 mm. long and 0.40 mm. wide and covered with eight rows of single-pointed spines, the eighth row not fully formed. The anterior half of the body is covered with tridentate and simple spines. Its general morphology is identical with that of the worm in case 1.

Case 4.—Nang Ch. L., female, Siamese, a housewife, resident of Bangkok, *æt.* 34, was very fond of petting cats, did not eat raw food, admitted into Siriraj Hospital, 7th July, 1932, on account of labour pains. Family and past histories were unimportant. The history of illness concerning gnathostomiasis was that previous to entry the patient had migrating swellings one at a time on the arms, legs and back for 6 or 7 months. The swelling varied in size, was always accompanied by inflammatory signs, itching sensation and boring or biting pain. Usually the swelling spontaneously disappeared within a few hours or a day and there were variable quiescent intervals. On 13th July, 1932, in the obstetrical ward she developed severe pain at the back of the right ear without any visible lesion for a few hours, and the pain then shifted to the back of the neck, left costal area and inside of the chest respectively, followed by slight irritation in the throat causing her to cough up about 10 c.cm. of bright red blood and a worm; after this the bleeding stopped and the symptoms disappeared. The whole duration was about 36 hours.

Parasite.—It is a male *G. spinigerum* measuring after fixation 4.20 mm. long and 0.77 mm. wide. The head bulb is 0.19 mm. long, 0.34 mm. wide and covered with eight rows of single-pointed spines which are not fully developed on the eighth row. The anterior third of the body is covered with tridentate and simple spines. Other general structure is identical with that of the worm in case 1.

Case 5.—Nang Soa Gn., female, Siamese, a house-keeper, resident of Bangkok, *æt.* 30, who always had cats in the house but gave no history of eating raw food. Her mother once had a creeping swelling which disappeared after extraction of a worm. Another female member of the family was also affected with a similar condition. For two years one patient had migrating swellings with inflammatory signs and slight itching on various parts of the body, these appeared one at a time. There was great variation in the subsiding period and in size. Each attack lasted about 2 to 3 days and usually quickly responded to hot compresses. One year previously she had extracted with a needle a worm from a tumour on her left breast. On

7th July, 1932, there was a slightly painful and tender mass 5 to 7.5 cm. in diameter over the left breast from which on 10th July, 1932, a worm similar to the former one was extracted with a needle by herself, and sent to us. Since then all symptoms disappeared and there was only a small black scab over the wound.

Fig. 3.—Photomicrograph of the tail of the parasite in case 5 showing spicules protruded from the posterior end and the posterior part of the body free from spines.

Parasite.—It is a male *G. spinigerum* measuring after fixation 9.35 mm. in length and 0.34 mm. in width. The cephalic bulb is 0.17 mm. long, 0.37 mm. wide and furnished with eight rows of single-pointed spines; the eighth row is not fully developed. The anterior third of the body is sparsely covered with single-pointed spines. General morphology similar to the worm in case 1.

Case 6.—Nang S., female, Siamese, a housewife, resident of Bangkok, *æt.* 27, who was very fond of petting cats. Family and past histories were unimportant. On 18th July, 1931, she felt fullness, slight itching and a painful sensation in the epigastrium. The itchy sensation spread to the left side of the chest accompanied by a slight diffuse shiny swelling. On the sixth day the left side of the neck was greatly swollen, very itchy and painful. The swelling spread to the chin and caused difficulty in turning the head. On the ninth day there were severe itching and pain at the root of the left ear with frequent forced coughing and expectoration that resulted in an expulsion of a living worm. There was no fever or headache. After expectoration of the worm the symptoms subsided in two or three days.

Parasite.—It is a male *G. spinigerum* measuring after fixation 4.68 mm. long and 0.77 mm. wide. The cephalic bulb is 0.14 mm. long, 0.40 mm. wide and covered with eight rows of single-pointed spines; the eighth row is not fully formed. The anterior third of the body is covered with tridentate and simple spines; general structure similar to the worm in case 1.

Case 7.—Nang L., female, Siamese, a house-keeper, resident of Bangkok, *æt.* 57. Clinical history was not available. The worm was extracted by the patient from a swelling in the left axilla on 26th August, 1932.

Parasite.—It is a male *G. spinigerum* measuring after fixation 4.93 mm. long and 0.85 mm. wide. The cephalic bulb is 0.17 mm. long, 0.43 mm. wide and covered with

eight rows of single-pointed spines; the eighth row is not fully formed. The anterior half of the body is covered with tridentate and simple spines; general structure similar to the worm in case 1.

Case 8.—Nai S, male, Siamese, a clerk, resident of Bangkok, *æt.* 26. Family and past histories in connection with gnathostomiasis were negative. About three months before attending the out-patient clinic of Siriraj Hospital on 21st January, 1933, the patient noticed a painful and itchy swelling on the left side of the abdominal wall, lasting a few days. Later similar swellings occurred successively on the right breast and neck. Examination revealed a superficial hard tumour about 2.5 cm. in size on the neck just below the angle of the right mandible with a reddish cord-like mass at the middle part. There was no enlargement of the cervical lymph nodes. Fæcal examination was negative for intestinal parasites.

Under local anesthesia the tumour was removed 'en masse' by Dr. Lek Sumitra, the surgeon in charge, and

dissection revealed a living worm embedded in the dense, gray, firm tissue.

Histology.—Microscopic examination of the hæmatoxylin-stained sections of the tissue specimen discloses irregular, tunnel-like spaces containing granular pink-staining necrotic tissue and deeply-stained fragments of cellular nuclei. The surrounding connective and adipose tissues are extensively infiltrated with eosinophiles, mononuclear cells, some fibrin and occasional red corpuscles, the first greatly predominating. In the periphery there is perivascular infiltration of small round cells and a few eosinophiles.

Parasite.—It is an apparently full grown male *G. spinigerum* measuring after fixation 6.50 mm. long and 0.85 mm. wide. The head bulb is 0.20 mm. long, 0.34 mm. wide and furnished with eight rows of fully developed single-pointed spines. The anterior third of the body is covered with tridentate and simple spines. During dissection of the tissue the parasite was ruptured and coils of the testes protruded.

Total cases of human gnathostomiasis reported

Author	Year	Number case	Age	Sex	Race	Symptoms	Duration of attack
Levinson ..	1889	1	Adult	Female	Siamese	Breast abscess.	Not available.
Leiper ..	1909	1	Adult	Female	Siamese	Cutaneous node.	Not available.
Samy ..	1918	1	23	Male	Chinese	Swelling of right hand and finger, abscess formation on the right thenar eminence.	1 month.
Tamura ..	1921	1	41	Female	Japanese	Intermittent pricking pain and swelling of right chest.	4 days.
Robert ..	1922	1	27	Female	Siamese	Paroxysmal violent and frequent cough with irritation of pharynx.	1 day.
Robert ..	1922	1	28	Female	Siamese	Migrating swelling of hands and feet with difficult walking. Palpitation. Difficulty of respiration.	8 months.
Robert ..	1922	1	21	Female	Siamese	Hæmaturia. Hæmatemesia, œdema, slight fever and paroxysmal tenacious cough.	1 year.
Morishita ..	1924	1	43	Male	Japanese	Linear swelling of left thenar eminence with continuous pain.	3 days.
Morishita and Faust.	1925	1	26	Male	Japanese	Creeping disease of the right shoulder.	Few days.
Morishita and Faust.	1925	1	Adult	Male	Japanese
Maplestone ..	1929	1	26	Male	Mahomedan	Migrating swelling with signs of inflammation.	Few days.
Datta and Maplestone.	1930	1	20	Female	Hindu	Bloody discharge from right ear and pain. Sore throat. Simulating mastoiditis.	Few days.
Prommas and Daengsvang.	1934	1	34	Female	Siamese	Migrating swelling with itching and boring pain.	6 to 7 years.
Prommas and Daengsvang.	1934	1	22	Male	Siamese	Swelling of right side of face with slight irritation.	6 days.
Prommas and Daengsvang.	1934	1	34	Female	Siamese	Migrating swelling.	3 years.
Prommas and Daengsvang.	1934	1	34	Female	Siamese	Migrating swelling, itching pain.	6 to 7 months.
Prommas and Daengsvang.	1934	1	30	Female	Siamese	Migrating swelling and inflammatory signs.	2 years.
Prommas and Daengsvang.	1934	1	27	Female	Siamese	Swelling itching, pain and expectoration.	9 days.
Prommas and Daengsvang.	1934	1	57	Female	Siamese	Swelling of axilla.	Not available.
Prommas and Daengsvang.	1934	1	26	Male	Siamese	Migrating swelling with pain and itching.	3 months.
Prommas and Daengsvang.	1934	1	36	Female	Siamese	Itchy swelling.	Not available.

Case 9.—Nang Ch. L., female, Siamese, housewife, resident of Bangkok, *æt.* 36, who had no history of taking raw food. Dogs and cats were petted. Family and past histories were unimportant. The illness began (1933) with a transverse itchy swelling about 15 cm. in length on the anterior wall of the lower part of abdomen, which showed two days later a small reddish nodule about the size of a pea at the middle portion. The itching greatly increased and caused scratching, and on the third day the nodule ruptured, exposing the head of a worm which was extracted. The swelling then subsided and the wound healed in two days. She never had swellings on other parts of the body.

Parasite.—It is a male *G. spinigerum* measuring after fixation 6.50 mm. long and 0.85 mm. wide. The cephalic bulb is 0.20 mm. long, 0.34 mm. wide and furnished with eight rows of single-pointed spines. The anterior two-thirds of the body is covered with tridentate and simple spines. Other general structure is similar to the worm in case 1.

General considerations

We have added nine cases of human gnathostomiasis to the twelve cases previously reported by various authors. These bring the total to twenty-one, of which 14 were found in Siam (Levinsen, 1889, Leiper, 1909, Robert, 1922, Prommas and Daengsvang, 1933), one in Malay States (Samy, 1918), three in China (Tamura, 1921, Morishita and Faust, 1925), one in Japan (Morishita, 1924), two in India (Maplestone, 1929, Datta and Maplestone, 1930). In addition we have seen twenty cases clinically diagnosed as gnathostome infestation one of which was confirmed by extraction of a worm by the patient from the buccal mucosa after suffering from facial swelling for about one week, but unfortunately the patient had thrown the worm away. The disease is apparently confined to oriental countries, and is especially common in Siam. It occurs in both sexes at any age (20 to 57 years). Seven of the twenty-one cases were in males and fourteen in females. Probably both sexes have similar chances of infection.

The disease is ordinarily characterized by a migrating intermittent swelling of varying size which is usually painless but on certain occasions is more or less itchy and painful. Pain if present is boring or biting in character and in rare cases is severe enough to disturb night sleep. The swellings do not show pitting on pressure and underwent suppuration in two cases only (Levinsen, 1889, and Samy, 1918) probably on account of secondary infection. The regional lymph nodes are not involved unless there is added bacterial infection. There is no definite anatomical distribution of the lesions; they are found on the abdominal wall, chest, shoulder, face, hand and foot. In one instance the parasite simulated mastoiditis (Datta and Maplestone, 1930), and in our case 4 it presumably pierced through the tracheal wall producing hæmoptysis. As a rule the blood picture shows eosinophilia of varying degree but this is not a pathognomonic feature since it occurs in many other tropical diseases.

Though nothing is known with certainty regarding the mode of infection and transmission

of the parasite, recently Prommas and Daengsvang (1933) discovered the development of its larval form in a cyclops, and are carrying on further promising experiments, the results of which will be published later.

For treatment of the disease many methods were tried by different authors, for example external application of tincture of iodine, cold and hot compresses, quinine by the mouth and intramuscular injection, etc. None apparently surpass surgical intervention.

Acknowledgment

We thank the staffs of Siriraj Hospital for their co-operation and Dr. K. Chareonvedh and Dr. Luang Visetbhadaya of the Department of Public Health for sending us two specimens.

[*Note.*—In the annual report of the Calcutta School of Tropical Medicine, for 1931, Maplestone reported an additional case to the two cited in this paper. His note on the case is as follows:—

'A third case of infection with an immature gnathostome was seen in a man who had never been out of Bengal. In this instance the escape of the worm was preceded by swelling in the throat, which considerably interfered with swallowing; this was followed by the formation of a furuncle above the right eyebrow accompanied by considerable swelling of the surrounding tissues, causing pressure on the eyeball with protrusion of this organ and disturbance in vision. Finally, the worm escaped near the site of the furuncle on the forehead, and the condition began to subside at once'.

BORED-HOLE LATRINES IN THE HEALTH UNIT, PARTABGARH

By KASHI PRASADA, D.P.H.

Medical Officer In-Charge Health Unit, Partabgarh

Introduction

THE work of construction of bored-hole latrines was started by the Public Health Department of the United Provinces in the district of Partabgarh in January 1933. Till the end of September 1933, 313 latrines were installed. The work is being done under the direction and control of the medical officer in charge of the health unit who had made a study of such work in some of the health units in Ceylon.

Area

The work so far has been restricted to the health-unit area, in which health activities on an intensive scale are being carried on with the assistance of the Rockefeller Foundation.

The area forms a portion of the Gangetic plain. The soil is predominantly of clay and free from rocks. Sandy strata occur at some places in the subsoil, while beds of 'kankar' are met with occasionally. The mean annual rainfall is 40 inches and the subsoil water level is 30 to 60 feet below the surface of the earth.

Sites

In selecting sites the two points kept in view were that the latrines should be easily accessible and should be situated at least 50 feet away from wells. The sites of the existing surface privies, courtyards or other places within 30 feet or so of the houses proved quite suitable for the purpose.

I. Boring of holes

Apparatus used—	Price	
Borer (boring bottom) .. Rs.	40-0-0	(approx- imately)
Shaft (1½ inches steam pipe, 3 pieces totalling 25 feet) ..	34-1-0	
Handle for turning the borer ..	14-8-0	
Manila rope, ¾ inch to 60 feet length ..	15-0-0	
Gin block, 12 inches by 1½ inches ..	20-0-0	
Tripod ..	21-14-0	
Jumper (to loosen stiff soil or break up bricks) ..	43-8-0	
One-inch octagonal steel bar (2 feet by 10 feet) Sal-wood frame with 4 W. I. pegs ..	16-0-0	
Two spades with wooden handles ..	3-0-0	
Two buckets and a rope ..	5-8-0	
Hundred-foot measuring tape ..	7-0-0	
'Thela' for transporting boring apparatus ..	15-0-0	
TOTAL .. Rs.	235-7-0	

The borer is of special steel and was imported from America. The other articles were purchased in Lucknow or were available locally.

Personnel required

One mason overseer at Rs. 25 per mensem.
Five coolies at Rs. 8 per mensem.

Dimensions of holes

The holes were 16 inches in diameter and were bored to a depth of 20 feet. Seventeen holes with an average depth of 8.6 feet were abandoned due to 'kankar' or bricks. This number constitutes 5.1 per cent of the total number of holes attempted.

PLAN OF SQUATTING PLATE.

Number of holes

The number of holes bored successfully during a period of 9 months was 317. These holes were distributed as follows :—

In Bela municipality ..	111
In Katra Medniganj town area ..	25
In Partabgarh town area ..	63
In 21 villages ..	114

Thirty-four of the holes were bored in schools and the rest in private houses. No holes were bored to serve as public latrines.

Boring time

The time required to bore a hole in sandy soils was considerably less than that required for boring holes in hard clayey soils. The average boring time per hole worked out to be

five hours and three minutes. The average time to dismantle, transport and re-erect the tripod, and to carry tools and equipment from place to place was fifty minutes.

Casing

One hundred and eleven of the bored-hole latrines were constructed in sandy soil. The majority of these were made before the rains.

Boring a hole.

Latrines showing different kinds of superstructures.

Construction of squatting plates.

In none of these, however, has any collapsing of the walls been noticed so far.

As an experimental measure a easing of wire-gauze—a cylinder 12 feet high and 15 inches in diameter—was placed in one of the holes.

Seat

Almost all the latrines have been provided with seats of the squatting type. A squatting plate is placed directly over the hole.

Superstructure

Superstructures to afford privacy and protection from rain and sun are usually constructed by the people at their own cost. Bricks, thatch, mud and wood are the materials generally used for making the superstructures. Considering the comparatively short life—three to five years—of the bored-hole latrines it is not advisable to use costly material. The superstructures were so made as to rise directly from the edge of the cement plate. They thus enclose an area of 3 feet by 2.6 inches only, which proves quite sufficient. In the side walls there are ventilating holes just above the squatting plates as well as near the roof.

Construction of squatting plates

The squatting plates are made of reinforced cement concrete. The design recommended by a representative of the Rockefeller Foundation has proved very satisfactory. The plates are cast in a wooden mould. They are taken out after 24 hours, when foot-rests sloping forward are added. The face of the hole in the squatting plate is splayed outwards and downwards so that there is no soiling of the sides.

Dimensions

The squatting plates measure 3 feet by 2½ feet. They are dished 1½ inches from edges to centre and their thickness throughout is 2 inches. The hole is situated at a distance of 6 inches from the posterior edge and is 14 inches long. Its width is 5 inches in front and 6 inches behind; see illustration and drawing.

Requirements

	Price
Thatch shed for mason to work in, 20 feet by 14 feet	Rs 8-0-0
Galvanized iron sheet, plain, 3 feet by 8 feet to serve as a mixing platform for cement, sand and concrete	" 4-11-6
Two shovels	" 4-0-0
Two buckets and a rope	" 5-8-0
Four sets—teakwood frames (moulds)	" 48-0-0
Wooden stamper	" 0-8-0
Template (iron sheet)	" 3-6-0
Empty kerosene oil tin	" 0-6-0
Two 'taslas' of iron (basins)	" 1-8-0
TOTAL	Rs. 75-15-6

Materials required to make 40 squatting plates

Article	Amount	Price
Cement	8 sacs (12.5 cubic feet).	Rs. 23-0-0
Sand	16 sacs (25 cubic feet)
Concrete	32 sacs (50 cubic feet).	Rs. 3-8-0
Iron rods (½ inch diameter).	960 feet or 193 pounds (80 rods).	" 14-2-0
Oil for greasing the moulds.	5 pounds.	" 1-0-0
Solution of silicate of soda.	1 phial.	" 0-7-0
TOTAL		Rs. 42-1-0

Personnel required

One mason at Rs. 15 per mensem.
One coolie at Rs. 8 per mensem to assist the mason.
Two coolies at Rs. 8 each per mensem. They bring sand from the river, transport squatting plates and also reduce concrete to the proper size.

General remarks

Some of the latrines have been in use for about nine months. A bored-hole latrine which is properly looked after is free from offensive smell. Flies do not breed in it because of its depth. It provides a satisfactory and inexpensive method of disposal of human excreta (urine and solid matter). It is convenient, as it can be installed right in the house. It is cheap and requires very little space. One hole suffices for a family of 5 persons. Disinfectants or the services of a sweeper are not needed. The latrines are consequently growing popular.

Summary

Average cost of boring one hole	Re. 1-7-0
Average cost per hole of transporting and erecting boring apparatus	" 0-4-0

Average cost of transporting squatting plates	" 0-9-0
Average total cost per hole	Rs. 3-14-3

A Mirror of Hospital Practice

TOXIC EFFECTS PRODUCED BY COMBINED TREATMENT WITH ATEBRIN AND PLASMOCHIN

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)
LIEUTENANT-COLONEL, I.M.S.

and

A. K. M. ABDUL WAHED, M.B. (Cal.)

(From the Carmichael Hospital for Tropical Diseases, School of Tropical Medicine, Calcutta)

T. G. B., a young Anglo-Indian male, aged 25 years, contracted malignant malaria in 1927 and suffered from frequent relapses during the following two years in spite of repeated but insufficient administration of quinine. Combined use of quinine and esanophele relieved him a great deal and for the next two years except

for a few mild attacks he kept well. In October 1932 he had a severe attack of malaria lasting for 7 days and was treated with quino-plasmochin, three tablets daily for five days. During the following five months he took two tablets of quino-plasmochin a week as a prophylactic measure but in spite of this he had several slight attacks. Altogether he had taken about 55 tablets of quino-plasmochin.

The patient also had hookworm infection and suffered from low fever, loss of weight, loss of appetite, disinclination to work and mental depression. He was treated with chenopodium but his general condition did not improve.

Early in December 1933 he again got fever and was given one tablet each of atabrin and plasmochin three times a day for 5 days. As soon as he finished this course he had pain under the lower part of the sternum and in the epigastric region and had difficulty in breathing. He developed marked cyanosis of the lips and finger nails, and suffered from severe palpitation of the heart. These symptoms continued with intensity for 4 or 5 days and then gradually abated.

The patient was then admitted into the Carmichael Hospital for Tropical Diseases for investigation and treatment. Clinical examination did not reveal anything except that the finger nails and lips were still blue. The pulse rate was somewhat quick, but physical examination of the heart did not reveal anything abnormal. The blood showed eosinophilia amounting to 15 per cent, but nothing else abnormal could be detected. An electrocardiogram of the heart showed a slight increase in the P-R interval (0.14 seconds), potential of R wave in the second lead was increased (2.3 millivolts) and the heart rate was 94 per minute. The picture was that of an irritable condition of the myocardium. Nothing abnormal was found in the urine. A skiagram of the lungs showed extensive fibrosis and infiltration but von Pirquet's test was negative.

The interest of this case lies in the sudden development of toxic symptoms after the combined administration of atabrin and plasmochin in therapeutic doses. Quite a number of cases of poisoning by the combined use of these two antimalarial drugs have been recently reported in this country and it would appear that there is a distinct tendency for one drug to increase the toxicity of the other when given together; even fatal results are said to have occurred.

The cardiac symptoms in this case are also of interest. The patient suffered from severe palpitation and shortness of breath. Although he was not seen when these symptoms were at their height, the examination of the heart did not reveal any great damage to the myocardium. That the heart muscle was undoubtedly affected is shown by the fact that when examined a week later when the acute symptoms were subsiding, it still showed all the symptoms of markedly increased irritability.

CALCAREOUS DEGENERATION IN A UTERINE FIBROMA

By SATYAPRIYA MOZUMDAR, M.B. (Cal.)
F.R.C.S. (Eng.)

A MIDDLE-AGED woman about 45 was admitted with a tumour in the abdomen. The history was very vague, duration of symptoms being anything between 5 to 10 years with amenorrhoea for the same period. Evidently her periods

had stopped about the time she noticed the lump in her abdomen. She was fairly well nourished.

On vaginal examination before operation, a sound could not be passed into the uterus but this was put down to the tortuousness of the uterine cavity owing to irregular growth of the fibroid.

During operation, under percaïne (spinal) anaesthesia, the tumour was found fairly easy to remove as there were very few adhesions, considering the duration of the growth, and an ordinary supra-vaginal hysterectomy was performed. But while dividing the cervix, no oozing was discovered.

On trying to divide the tumour, after operation, it was found impossible to cut it with an ordinary knife deeper than the superficial half inch of tissue. Then an amputation knife was tried, with no better result. I had actually to use the chisel and hammer for nearly half an hour before I could cut the tumour across—it being practically completely calcareous with no uterine mucous membrane left, the whole uterus being involved in this degeneration. This explained the long period of amenorrhoea although the ovaries were healthy, and also the inability to pass the uterine sound and the absence of mucus exudation from the cut surface of cervix during operation. The tumour weighed about 6 lbs., although its size was only about 6 inches by 4 inches by 6 inches.

The patient made an uneventful recovery.

A CEREBRAL TYPE OF MALARIA LIGHT-ED UP BY A SUDDEN SHOCK

By CHINMOY LAHIRI, L.M.S.
D. B. Medical Officer, Rangpur

On the morning of the 15th October, I. M., a Mahommedan male, aged 13 years, had a fall and became unconscious.

I was called about 10 a.m. to see the patient and found him unconscious with irregular and violent muscular twitching, temperature 97.8°F., pulse irregular and feeble, respiration hurried, pupils slightly dilated but equal, sordes around the mouth, knee jerks present and other reflexes intact, and spleen enlarged about 2 inches below the costal margin.

There was no history of similar previous attacks, and the family history of syphilis was negative. The patient's father admitted that the boy had three or four attacks of malaria prior to this illness. So I suspected it might be a case of cerebral malaria set up by a sudden shock and at once injected grains 10 of quinine bihydrochloride intramuscularly. No other medicine was prescribed as the patient was unable to swallow. The patient had a rise of temperature to about 104°F. shortly after the injection. Another dose of grains 10 of quinine was injected the same evening at about 8 p.m. Next morning the general condition was slightly improved though the boy was still unconscious with muscular twitching persisting at long intervals. I gave him 0.1 gramme of atabrin dissolved in 10 c.c. of normal saline intravenously at about 9 a.m. About midnight the patient regained his senses and his temperature came down to normal. He was then put on a course of atabrin along with a simple alkaline mixture and made an uninterrupted recovery within a week.

I am thankful to Dr. S. K. Sirkar, District Health Officer, for kindly permitting me to publish this case note.

[Note.—Although there is strong presumptive evidence that this patient was suffering from malaria, it seems to us that the condition may only have been one of severe concussion. Further, the history does not make it clear that the fall was not due to the loss of consciousness.—Editor, I. M. G.]

Indian Medical Gazette

APRIL

THE TOTAL CINCHONA ALKALOIDS

THE employment of the total cinchona alkaloids in the treatment of malaria is so largely an economic question that whenever it is raised at a medical conference, someone invariably kills any discussion by pointing out that it has gone beyond the scope of such a conference. We have never been privileged to attend the deliberations of those responsible for the finances of either India or any of its provinces, but we have little doubt that when these are concerned with the policy of the country or province with regard to the cultivation of cinchona, and the provision of a cheap malaria treatment for the people, they are frequently hampered because these experts find themselves led into discussions that are primarily medical.

The consequence is that no particular policy is adopted, and that we muddle on year after year; India produces only a small fraction of the drugs she requires yearly for the treatment of her malaria-stricken population, and there seems no prospect in the near future of her being able to reduce the discrepancy between her production and her requirements, yet there are in this country large tracts of land suitable for the cultivation of cinchona bark, which if planted now would make India entirely independent of foreign quinine, or other antimalarials, within a very few years, and would provide a very considerable margin for export.

There is a never-failing supply of excuses for inaction in this matter, but one that has been used frequently during the last few years has been that the League of Nations' Health Organization is considering the matter.

The report of the League of Nations' Malaria Commission on this particular subject appeared last June in the *Quarterly Bulletin of the Health Organization*.

In our last issue we discussed this report and reprinted extracts from it. Further extracts will be found in our present issue; these include the opening paragraphs of the report in which the general aims of the commission are set forth. To those who have followed the cinchona-alkaloids controversy and have awaited this report of the commission with high hopes that an authoritative statement would be produced, these paragraphs provide almost tragic reading, in view of the nature of the rest of the report. One's hopes were raised to a high level because one felt that the problem, as it exists in India to-day, seemed to be so fully understood; no words could express India's needs better than do the following, which are quoted from this section of the report:—'The

aim of large-scale antimalarial effort by means of drugs is not concerned with providing a medicine which is the most effective antimalarial remedy known to medical science. What is aimed at is to provide a remedy that is so abundant and can be obtained so cheaply that it can be made readily available to the whole population of malarious countries. The endeavour of the Malaria Commission is to arrange a scheme of that kind. In such a plan there is no question of providing the most effective remedy known, nor even, necessarily, of providing a remedy as effective as quinine. The object is simply to provide, preferably by local cultivation of *C. succirubra*, or by other action in the malarious countries themselves, an abundant supply of a medicine, which will mitigate the severity of malarial attacks and prevent the disease from terminating fatally'.

Having thus shown that they understood what was the most urgent requirement of malaria-stricken nations, the commission then proceeded to devote almost the whole of the rest of the report to secondary matters. There is certainly reference, to the composition and standardization of totaquina (but this, though it was the work of the commission, is now old history), to certain experiments with the total alkaloids in bird malaria carried out by Professor Giemsa, to the results of treatment in five cases of induced malaria with each of the two varieties of totaquina, and to the difficulties of clinical investigation (in this connection they have drawn up certain rules to be observed for testing totaquina clinically); but otherwise they appear to have been lured away from their main purpose by the glitter of the new synthetic antimalarials. We should be the last to deny the extreme value of the work that was reported upon, as far as the treatment of the individual malarial patient was concerned, but it has left the problem that they set forth in the first paragraphs of the report exactly where it was before.

Many of our readers will be familiar with the total-cinchona-alkaloids problem, but, for those who are not, we will give a brief résumé of the main points. Cinchona bark contains a number of alkaloids; of these quinine is the one that has achieved most popularity in the treatment of malaria and is therefore most in demand. This has led to the cultivation of the particular species of cinchona tree that will produce bark giving the highest yield of quinine, but it is not a hardy species and it will only grow in certain areas; in India these areas are very limited. Nevertheless, while the main demand is for quinine only, it is not an economically sound policy to grow, even in India, any but *Cinchona ledgeriana* with its high quinine yield. However, it has been shown that the other alkaloids of cinchona bark also have antimalarial properties; it has been claimed by some workers that with certain species of plasmodium the action is even

greater, and it is generally acknowledged that the action on any species is only slightly less, than that of quinine. If therefore all the alkaloids of cinchona were utilized in the treatment of malaria, the amount of antimalarial drug that could be extracted from each pound of cinchona bark would be much greater and, further, it would become unnecessary to use only the special tree giving a high quinine yield, and harder species, such as *Cinchona succirubra*, which give a high yield of the total alkaloids, could be planted extensively. Not only is this mixture of the alkaloids of cinchona bark cheaper than the pure alkaloid quinine, but, if it were in demand, it could, after the few years which would be necessary for the extension of the plantations, be produced in almost limitless quantities in this country. Exactly why it is not in demand, it is difficult to say, but there is no doubt that 'cinchona febrifuge', a generic name applied to all mixtures of the cinchona alkaloids, has never achieved any real popularity though in certain provinces in India it has been, and is still, used extensively. One reason undoubtedly is that from time to time various mixtures of the residue from quinine manufacture have been placed on the market and labelled 'cinchona febrifuge'; these mixtures contain very little quinine, and an abundance of the amorphous alkaloids which are not only practically inactive but tend to make the tablets of cinchona febrifuge hard and insoluble.

The introduction of this new standard mixture of the cinchona alkaloids, totaquina, is a very definite step in the right direction. It will not be an exact mixture of the alkaloids but one whose composition varies within certain limits: these limits are sufficiently rigid to allow the clinician to advocate a standard dosage from which he may expect a response that will vary only within the usual range of clinical experience with quinine, and at the same time will not be so rigid as to complicate manufacture or to prevent the mixture from being made directly from the hardy *C. succirubra* or *C. robusta*, without the addition of alkaloids from another source.

These observations refer to totaquina (type I). We cannot, however, see why the commission found it necessary to complicate matters by introducing a second type; the only useful function totaquina (type II) appears to perform is to provide the quinine manufacturer with a means of disposing of his residue. The few tests that have been made suggest that this type II displays a very low degree of efficacy, and we think it is a pity that the name 'totaquina' should have to bear the stigmata that it will acquire if the quinine manufacturers are allowed to place this poor-quality antimalarial on the market under this name.

In view of the fact that the areas where *C. ledgeriana* grows well are limited and that these areas are mostly in Java, the Dutch

planters exercise a complete control over the quinine market of the world. At present there is a glut on the quinine market, but, by virtue of this control, the high price has been maintained. When we say 'glut' we do not mean that there is more quinine made than is required, but more than malaria-stricken nations can afford to pay for; India cannot afford to buy more than about one-tenth her real requirements. We may therefore assume that foreign cinchona planters and quinine manufacturers will be definitely ranged against the suggestion for the widespread use of totaquina, but those in control of the plantations and factories in this country, which are all government-owned, are both willing and anxious to co-operate if they can get a clear lead from the medical profession; this would be indicated by an increasing demand for totaquina.

The uncertainty regarding the composition of the cinchona-alkaloid mixtures, which has been the excuse used by medical men in this country for adhering doggedly to quinine, now no longer holds good if totaquina (type I) is prescribed, and one hopes that when this product is generally available we shall see an increase in the demand for the total alkaloids of cinchona.

Outside medical circles there is a distinct feeling that the substitution of 'cinchona febrifuge' for quinine in provincial dispensaries is an attempt to foist an inferior article on to the poor. For this entirely wrong interpretation, the medical profession must bear some of the responsibility, as public opinion in such a matter is naturally influenced by medical opinion.

Trials that have been conducted with total-alkaloid mixtures at Kasauli and elsewhere in this country have shown that for practical purposes they are equal to mixtures containing the single alkaloid quinine. The League of Nations' Malaria Commission have confirmed this in the following words:—'It appears from these results that totaquina type I (total alkaloids of *C. succirubra* or *C. robusta*), when used in ordinary clinical therapeutic doses for curative purposes—e.g., 1.2 gm. (20 grains) daily for five to seven days—should give about the same good result as is given by quinine in the same doses. If this is so, and if this type of totaquina can be obtained more cheaply than quinine, it would be advantageous to use it for general purposes instead of the single alkaloid.

However, in view of the extreme paucity of the trials that were conducted under their auspices and of the lack of prominence given to this conclusion, it cannot carry much weight, and we feel that a wonderful opportunity of placing this question of the efficacy of the total-alkaloid mixtures beyond any possible doubt, and of making a really authoritative pronouncement on the subject has been missed.

If a commission of the League of Nations, whose expressed purpose was to investigate this problem and who fully understood the position in India to-day, failed to produce an

authoritative answer; one almost despairs of this ever being given; yet until it is given we can expect no progress in the matter of the cinchona policy in this country.

REPORT OF THE THIRD CONFERENCE OF THE ALL-INDIA OPHTHALMOLOGICAL SOCIETY

THE Third Conference of the All-India Ophthalmological Society was held in the auditorium of the All-India Institute of Hygiene and Public Health, Calcutta, from the 19th to the 21st December, 1933. The attendance was the largest on record and was well supported by large numbers of delegates from all parts of India. Dr. A. Fuchs from Vienna and a number of other visitors attended the Conference.

The Conference was formally opened by Sir Hassan Suhrawardy, M.A., F.R.C.S., Vice-Chancellor of Calcutta University, in an excellent speech in which he pointed out the absence of facilities for ophthalmological work in India and regretted that this vast country was still very backward in the number of well-equipped and modern ophthalmic hospitals. The enormous ophthalmic centres in the capitals of the various provinces of India were maintained at Government expense, and, in each, magnificent work has been and is being done, but he hoped that wealthy Indian gentlemen would come forward with sufficient money for the establishment of further ophthalmic hospitals and schools where efficient post-graduate training and research could be carried out.

In welcoming the delegates, Dr. D. N. Maitra, chairman of the Reception Committee, said that the problems of health which included that of the eye were at the bottom of social education and economic problems.

Lieut.-Col. J. N. Duggan (Bombay) was formally proposed to be president of the Third Conference by Lieut.-Col. E. O'G. Kirwan (Calcutta) and seconded by Dr. G. Zachariah (Madras).

Lieut.-Col. Duggan, after acknowledging the honour paid to him in being elected to the office of president, gave in his address a comprehensive survey of the progress which ophthalmological science has made in recent years, and stressed the need for a well-organized and systematic campaign for the prevention of blindness in India as much of the blindness is preventable and yet there are enormous numbers of blind and partially-blind people all over the country. He pointed out that India had earned a place in ophthalmology in the past. The intracapsular method of cataract extraction and sclero-corneal trephining for the relief of glaucoma have been two notable contributions to operative surgery. He acknowledged the work done in the clinical, pathological and operative lines by distinguished members of the Indian Medical Service who had gone far to raise the status of Indian ophthalmology, and pleaded that this work must be continued hereafter if the prestige of Indian ophthalmology is to go still higher. In concluding he reiterated that, as there is such an abundance of clinical material available in all parts of India, research should be encouraged on thoroughly scientific lines.

In the afternoon the scientific session was opened by a paper on epidemic superficial punctate keratitis in Bengal by Lieut.-Col. E. O'G. Kirwan. After describing in detail the clinical findings, pathology and treatment, he pointed out that the name superficial punctate keratitis was a misnomer as in a large number of these cases the affection produced a mild iridocyclitis. He therefore favoured the suggestion of Lieut.-Col. R. E. Wright that it should be called keratitis

diversiformis et uveitis anterior. The paper was illustrated by slit lamp paintings.

An interesting paper on the treatment of spring catarrh by injections of foreign proteose emulsion from the urine by Dr. Banaji (Bombay), produced a lively discussion in which a large number of members took part.

Dr. Fuchs (Vienna) read a paper on the surgical treatment of iritis.

This was followed by a paper on Parinaud's conjunctivitis by Dr. Sanyal (Calcutta) which was illustrated by lantern slides. The afternoon session closed with a paper by Dr. Bhaduri (Calcutta) on observations on the leprotic affections of the eye in which he pointed out the causes of the wide variation of the ocular incidence in leprosy and advocated the benefit of iridectomy in the early stages of iritis.

In the evening a magic-lantern-slide and cinema demonstration was given by Lieut.-Col. E. O'G. Kirwan, on prevention of blindness and care of the eyes in India.

The second scientific session was held on the morning of the 20th December, 1933, and among the most interesting papers was one by Dr. S. K. Mukerjee (Calcutta) on further observations in glaucoma as a result of epidemic dropsy, which comprised tonometric, ophthalmoscopic and visual field studies.

The president of the Conference, Lieut.-Col. Duggan, read a very instructive paper on the treatment of external eye diseases with ultra-violet light.

Dr. J. Gnanadikam's paper on iridencleisis was most instructive and in it he pointed out the advantages of this operation over other methods of decompression from his experiences of a large number of cases. It was clearly evident, from the discussion that followed, that the operation of iridencleisis has many advocates in India, although most ophthalmologists favour sclero-corneal trephining in chronic primary glaucoma in the majority of cases.

An interesting paper which stirred up a hornet's nest was one by Dr. S. N. Shroff on the intracapsular cataract operation suitable to the conditions in India in which he stated from his personal experience that the expression operation of Lieut.-Col. Smith with certain modifications is the most suitable to the conditions in India where there is such a large amount of work to be done in a limited time. He pointed out that in all cases the lens should be tumbled but in cases in which there was a strong zonule capsulotomy should be done.

The Madras school of ophthalmology produced a most interesting paper by Lieut.-Col. R. E. Wright and his staff on von Hippel-Landau's disease. There were only three cases seen out of more than a quarter of a million fundus cases examined in Madras. Two of the cases were followed up for a long period; in all cases the changes observed were only in the retinal vessels on one side and there was no evidence of a familial nature, nor of the central nervous system or any skin affections.

The third scientific session took place on the afternoon of the 20th December, 1933, and among the most interesting papers read was one by Dr. Bhaduri (Calcutta) on some observations on hypotension in cholera in which he showed tonometric records in 46 cases, and that the blood specific gravity varies inversely with the intraocular tension. Capt. K. Sen

(Calcutta) read a paper on the asepsis of the conjunctival sac in intraocular operations, in which he stated that 64 per cent of the conjunctival sacs before intraocular operations showed no growth in 48 hours culture, and of the remaining 36 per cent, one-half showed harmless organisms and the remainder streptococci, staphylococci, etc. He advises the use of mercuriochrome drops one per cent, irrigation of the conjunctival sac with 1 in 10,000 oxycyanide of mercury and, immediately before operation, irrigation of the sac with normal saline. A lively discussion followed in which many members took part.

Perhaps the most interesting paper in this session was read by Capt. S. C. Dutt (Calcutta) on the development of modern ophthalmology in Bengal in which he surveyed the period extending from the time of the Honourable East India Company in 1796 to the present day.

The fourth scientific session took place on the morning of the 21st December and among the most interesting papers was one by Lieut.-Col. E. O'G. Kirwan on blue sclerotics in which he pointed out the paucity of cases in this vast country. He illustrated two cases with coloured sketches and discussed the different views on the causation.

Dr. Rafatullah's paper on Webster's operation for entropion produced a keen discussion and the author advocated his mucous graft operation as a foolproof method in the cure of this common and troublesome complaint.

Dr. H. K. Indra (Calcutta) read three short papers on lenticulus posterior, Kruekenberg's spindle and a case of aphakia with apparent accommodation. All these papers were beautifully illustrated with slit lamp paintings carried out at the Eye Infirmary, Medical College, Calcutta.

The fifth scientific session took place on the afternoon of the 21st December, 1933, and amongst the outstanding papers of interest were Dr. Biswas' (Calcutta) notes on a few cases of epidermoid carcinoma, a paper by Capt. N. N. Roy (Calcutta) on septic thrombosis of the cavernous sinus and orbital cellulitis, the after treatment of cataract by Dr. N. Chatterjee (Calcutta) which produced a lively discussion in which many members took part. Dr. J. N. Banerjee (Calcutta) read a comprehensive paper on school myopia in Bengal.

The annual general meeting of the All-India Ophthalmological Society took place on the evening of the 21st December at which a resolution advising more thorough legislation on the proper examination of the

eyesight of drivers of motor vehicles was moved by Dr. Narayan Rao and carried unanimously. It was also resolved to draw the attention of some of the universities in India to the absence of a special paper in ophthalmology in the final examination in medicine.

The following office-bearers were elected:

President	Lieut.-Col. J. N. Duggan, C.I.E.
Vice-Presidents	Lieut.-Col. R. E. Wright, C.I.E., I.M.S. Lieut.-Col. E. O'G. Kirwan, I.M.S.
Secretaries	Dr. G. Zachariah, D.O.M.S. Dr. B. N. Bhaduri.
Treasurers	Dr. S. N. Shroff, D.O.M.S. Dr. K. N. Karanjia, F.R.C.S.

It was decided that the next meeting of the All-India Ophthalmological Society should take place during the Easter week of 1935 in Madras, and the subject for discussion should be nutritional disorders of the eye.

The congress was finally brought to a close on the night of the 21st December when it ended with a dinner at the Great Eastern Hotel at which many delegates and members were present, and the general impression was that the congress was a great success, and had led to much mutual understanding and co-ordination not only in the working out of scientific problems, but in bringing together workers from various parts of India.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

HIS ROYAL HIGHNESS THE PRINCE OF WALES has graciously consented to become patron of the London School of Hygiene and Tropical Medicine, with which is incorporated the Ross Institute. This gratifying announcement was made at the staff and students' dinner by Sir Austen Chamberlain, the chairman of the Court of Governors.

NOTICE

From time to time we receive requests from book-sellers, particularly in Europe and America, for back volumes of the *Gazette*.

We have recently received such an enquiry for volumes 1 to 47. Readers who have any early volumes for sale are invited to forward details to us.—Editor, I.M.G.

A Review of Published Results obtained with Atebrin in the Treatment of Malaria in Malaya (Part VI. Summary and Conclusions)

By A. L. HOOPS, C.B.E., M.D., D.P.H.

(From the *Malayan Medical Journal*, December 1933, Vol. VIII, p. 232)

DUNCAN, BARROWMAN and HOOPS have reported on the treatment of 2,219 members of labour forces, including dependents, with atebrin alone or with atebrin and plasmoquine.

Adequate oiling was maintained on most of the areas inhabited by the labour forces. All original cases treated for further attacks of malaria were reckoned as relapses. Nearly two-thirds of those treated, 1,418 cases, were kept under observation, by Duncan and Barrowman for over 6 months, by Hoops from 3 to 15 months.

Although not diagnosed microscopically as malaria the relapse rates in unclassified cases quoted by Hoops are given because there will always be some estates without microscopes, and also odd cases of clinical malaria will occur in which the parasite is not easily demonstrable. These rates were 10 per cent amongst 60 persons treated with atebrin only and 7.4 per cent amongst 54 persons treated with plasmoquine and atebrin. Barrowman shows the same relapse rate, 5 per cent, in his subtertian cases treated with atebrin only and with atebrin plus plasmoquine. Second relapses were very rare in both benign tertian and subtertian types. From the results obtained the treatment of malaria with atebrin should be the method of choice in Malaya. Whether it is to be followed by a course of plasmoquine or not is really a public health problem depending principally on the effectiveness of the oiling in the area where the person treated is living. Atebrin treatment by the eradication of the schizonts prevents the formation of the later generations of gametes. The earlier broods of gametes will die out in a few weeks.

Whether plasmoquine should be given to kill the latter, depends therefore on the risk of infection being conveyed to others in any particular estate. In this several factors are involved—the number of persons with gametocytes in their blood; the number of malarial-carrying anophelines present (most important); the number of bites received from infected mosquitoes; the intensity of the infection conveyed. A change in the level of the surface water, an influx of unhealthy new labourers or the felling of a new area may necessitate the adoption of measures not previously needed.

The Malarial Commission's report (pp. 236-237) suggests that the percentage of malarial cases containing gametocytes in their blood may at times be as low as 1 per cent though in children it may be 17 per cent or more. But Green, in a series of 1,000 subtertian cases, found that over half carried crescents in the proportion of one or more per 200 leucocytes and were therefore potentially infective to *A. maculatus* (*Bulletin I. M. R.*, No. 5 of 1929). If these high rates are common in Malaya the argument for giving plasmoquine is strengthened.

Green found also that gametocytes seldom appeared before the 6th day in new infections and took on an average nearly 8 days to disappear under treatment with plasmoquine compound—the limits being 4 to 13 days (*Bulletin I. M. R.*, No. 3 of 1929). It may be assumed therefore that the treatment with plasmoquine simplex now in vogue should not be started before the 7th day in primary attacks, and that with an adult a dosage of between 0.03 gram and 0.02 gram daily should be continued for 7 or 8 days.

Remarks on quinine treatment

The condemnation of long courses and large doses of quinine by the League's Malaria Commission is welcome. The poisonous effects and the deterioration in efficiency caused thereby are well known.

The practice of clinical prophylaxis with daily quinine, mentioned in this report for use in countries where it is not considered practicable to use a proper system for the prevention of relapses, has no place in Malaya. Here the dark ages, when many Europeans took quinine daily during residence and for several months after returning home, are gone for ever.

Generally speaking under any system of quinine administration relapse rates of 50 per cent have been regarded as common, and of 33 per cent as satisfactory. Reference is invited to the various experiences of Duncan and Barrowman. With a short course of 10 days quinine—comparable to the 5 to 7 days course advocated in the League's report—without after treatment—Barrowman's relapse rates amongst 412 subtertian and benign tertian cases averaged 90 per cent. Though long courses are objectionable it is impossible to rely on such a short course for use among labour forces, for widespread infection would result.

I would suggest to those medical men who still prefer to use quinine instead of atebirin the trial of a 7 days course in hospital of from 20 to 30 grains of quinine bihydrochloride daily, followed, after intervals of two weeks each, by two or three supplementary courses of ten grains daily for a week, given in the lines. This would doubtless help to reduce the very high relapse rate met with by Barrowman, especially if a course of plasmoquine were given also. But low relapse rates cannot be expected with quinine.

Following the League Commission's comparison between the relative costs with quinine and with atebirin of a 5 to 7 days course for the clinical cure of a primary attack of malaria, the Amsterdam Bureau for Increasing the Use of Quinine claims, in a propaganda pamphlet, that to use quinine rather than atebirin for the cure of malaria is several times cheaper. But a comparison of immediate costs takes no account of the real effectiveness of each treatment, of the relative proportion of relapse rates, and of the resulting final costs for further treatment both of the original case and new infections, or of the resulting dislocation of work and loss of efficiency amongst labour forces.

Referring to the cost of the primary course of treatment only, Kingsbury states (1932 report of the F. M. S. Malaria Advisory Board):

'The present cost of quinine sulphate is \$16.50 (Straits) per lb. A bottle of 300 atebirin tablets costs about \$1 more. A pound of quinine sulphate was sufficient for treating 36 cases for a period of 7 days. The bottle of 300 atebirin tablets was sufficient to treat 14 cases for 7 days. The 7 day course of treatment with quinine sulphate costs about 45 cents while a 7 day course of treatment with atebirin costs \$1.23. If, on the other hand, a large quantity of atebirin tablets, say 10,000, were purchased, the cost of treating a case with atebirin for seven days was then 61 cents, as compared with 45 cents for quinine-treated cases'.

In this country during the gradual development of natural immunity to malaria many persons die: many of the survivors get enlarged fibrotic spleens, chronic nephritis, general debility, low haemoglobin, and become more prone to contract heavy ankylostome infections, bowel diseases and tuberculosis. They also spread infection to others. The avoidance of such risks by a short treatment with atebirin is true economy.

Conclusions

1. Atebrin is the best drug available for the treatment of all types of malaria in Malaya.

2. Though users of atebirin differ on this point it is not in my opinion advisable or beneficial to give quinine as a routine before commencing atebirin treatment.

3. Atebrin is as efficacious as quinine in abating the clinical symptoms of the primary attack of malaria.

4. Atebrin is infinitely superior to quinine in the prevention of relapses: judging by present records it may be expected to effect a radical cure in nearly 90 per cent of benign tertian and 95 per cent subtertian cases. If the relapse rates with it were twice as high it would still be the drug of choice.

5. For this reason it is a cheaper drug to use than quinine. Ross wrote 'The question of what are cheap and what are expensive measures is a comparative one and depends principally on what is the cost of the disease'. Barrowman's figures show conclusively that the cheapest method of combating malaria is to oil the danger zones and treat the cases with atebirin.

6. Relatively larger doses of atebirin are needed to cure children than adults: these doses are well borne.

7. In serious cases of malaria the injection of atebirin is probably as effective as the injection of quinine bihydrochloride.

8. Toxicity—the toxicity of atebirin is low. The same amount of supervision is necessary as should be given when quinine is used.

9. The ambulatory treatment of malaria should be discouraged. Cases do better in hospital and there is less risk of infecting others.

10. Plasmoquine if used should preferably not be administered until after the atebirin course is finished.

11. Further observations are needed as to the results obtained (a) with atebirin only and (b) with atebirin followed by plasmoquine.

12. Routine treatment of persons with enlarged spleen. It appears that routine dosing of all such persons with either quinine, plasmoquine or atebirin is wasteful and unnecessary. It is suggested that the blood and temperature should be taken and treatment given only if there is a positive indication.

13. Oiling. The practice of oiling should be continued even if labour forces are treated with atebirin. It is a question for the future whether the sterilization of the blood of labour forces with this drug, combined with research into the seasonal prevalence of malaria-carrying mosquitoes, may enable oiling to be restricted in some places during certain months.

Neurological Emergencies

By WILFRED HARRIS, M.D. (Camb.)
R.N.C.P. (Lond.)

(Abstracted from the *Lancet*, October 14, 1933, p. 840)

FITS

Fits of various kinds, or coma, due to many different causes, are a common cause of difficulty, and a correct diagnosis will often mean the saving of a life.

You receive an urgent call, and find a middle-aged man, or woman, lying quite unconscious, perhaps at the foot of a staircase. If you know the patient is the subject of epileptic fits, your diagnosis may be easy, but you have to consider even then whether the patient fell in a fit before going upstairs, or whether a severe fall downstairs has caused a fractured skull, or whether it is a case of primary cerebral hæmorrhage. Evidence of bleeding from scalp or ear, or bruising, will indicate a fall, and further evidence of unequal pupils, conjugate deviation of the eyes, twitching of face or limbs, or signs of hemiplegia, may clinch the diagnosis of cerebral injury. The position of the patient relative to the surroundings should be noted before his removal to a couch or bed. What next is to be done? All clothing should at once be loosened, and then removed, and the patient put to bed with hot bottles, well wrapped in a blanket, to the feet. Never forget the danger of a hot-water bottle burn in these conditions. The odour of the breath may give a clue, an alcoholic smell suggesting possible drunkenness as the sole or contributory cause of the coma, but you must remember that a single glass of beer or cider taken two or three hours previously may be sufficient to taint the breath heavily. This is particularly important for police surgeons to remember in dealing with patients accused of being under the effects of alcohol to a degree rendering them incapable of being in charge of a car.

A highly nervous man too in such circumstances may stammer, and also sway in walking when under examination at the police station, or, a more difficult trap for the unwary, he may be the subject of slight ataxy from various causes, such as early tabes or combined sclerosis, cerebellar ataxy, or even aural vertigo.

The presence of definite nystagmus, especially if in one direction only, will indicate a lesion of the cerebellar system, but beware of diagnosing nystagmus from slight quick irregular movements of the eyes at the commencement of lateral deviation, especially in a nervous individual. Remember, too, that spontaneous nystagmus in all positions may be of congenital origin, such as albinism.

Conjugate deviation of the eyes may be either irritative or paralytic in origin. It is a common teaching that the eyes are turned towards the lesion in the brain in apoplexy, that is to say, that there is paralysis of the conjugate movement towards the opposite side, with unopposed action of the similar movement away from the sound side towards the side of the lesion. Deviation of the eyes may, however, be irritative from the lesion, and slight rigidity or even convulsions may be seen on the side that will be ultimately paralysed, and in this case the conjugate deviation of the eyes will be towards the sound side of the brain and away from the lesion, during the stage of cerebral irritation, ultimately swinging back towards the side of the brain lesion. Thus, in the early stages it is quite possible to diagnose the lesion on the wrong side of the brain.

The pupil reactions to light are a frequent source of error. Often they are said not to react when they are really normal, the test being carried out in a moderate or brightly lit room, with insufficient precautions. Beware of the small pocket torch as a test. Either a strong torch or electric light, or a bright

window light should be used, both eyes being properly shielded for a few seconds before testing. Repeat the test, exposing each eye separately. Very small pupils will suggest opium poisoning, pontine hæmorrhage, or the Argyll Robertson pupils of tabes. Unequal pupils will suggest a gross cerebral lesion, such as cerebral contusion or hæmorrhage, but the Argyll Robertson pupils of tabes or G.P.I. are often unequal.

To return to our unconscious patient, now in bed. An x-ray of the skull is important if the possibility of fracture has to be considered. This can be very efficiently done at the patient's house nowadays by portable apparatus of a special outfit driven by the car engine.

Depressed fracture, either in children or adults, is most important to recognize, though it may not be palpable as such, possibly only a lump being felt. The signs of cerebral injury, however, an irregular or slow pulse, slow or Cheyne-Stokes' breathing, unequal pupils, or squint, should indicate a graver type of cerebral injury than mere concussion, and pointing to either severe contusion, laceration, or compression from fracture or hæmorrhage. If, then, there is a definite lump or gross irregularity of the skull, it will be advisable not to wait for an x-ray, but to proceed at once to shave and sterilize the area of scalp concerned, and to cut down upon the bone to make certain of its condition, when a depression may be often quickly dealt with and a life perhaps saved.

Concussion may be followed by recovery of consciousness, and later may be followed by delirium, increasing drowsiness, and coma. This condition indicates the onset of cerebral oedema as a sequel of contusion of the brain and of numerous minute hæmorrhages, possibly even laceration of the brain in more severe injuries. Lumbar puncture will almost certainly show yellow staining from altered blood, or even the cerebrospinal fluid may be mixed with fresh blood, the pressure of the fluid being high and registering 200-300 on the manometer. This is a very important stage to recognize, as the patient will almost surely die if left alone. A decompression operation must be done at once, a large bone flap being raised, so as to allow of expansion of the oedematous brain. There may be no localizing sign or indication on which side to operate, in which case a right subtemporal decompression should be done. In a few cases the cause of the cerebral compression will be found to be an extradural hæmorrhage from a torn middle meningeal artery, but then there is almost always some local indication on which side to operate.

Lumbar puncture, too, may settle the question of cerebral hæmorrhage, the fluid being intimately mixed with blood. The inexperienced may in such a case mistake the mixed blood and fluid for blood from a punctured vein, and be unaware that his needle has correctly pierced the spinal theca. More accurate information can be obtained by using a special spinal needle with manometer attached to read the pressure. If the fluid rushes up the tube past the normal 140 or 150 mm. mark to 250 or more, then severe intracranial pressure is evident. Beware then of withdrawing more than the minimum of blood-stained fluid, as fall of pressure might start fresh cerebral hæmorrhage.

Examination of the optic discs should be done as soon as convenient, as clues to the condition may be found in retinal hæmorrhages, large or small, albuminuric retinitis, or the choked discs of cerebral tumour. In the latter condition immediate benefit may result from dehydration by intravenous injection of 3 oz. of 15 per cent salt solution, or, if that method is not possible, the rectal injection of 8 oz. of a 25 per cent solution of magnesium sulphate.

COMA

The causes of coma are too numerous for us to examine them all. In epileptic coma the patient lies flaccid with dilated pupils and stertorous breathing,

somewhat livid in colour, no conjunctival reflex, the tongue possibly bitten, with blood around the lips, and evidence of relaxed sphincters. After two or three minutes in this state he may quickly recover, or may go off into a heavy sleep for three or four hours.

Narcolepsy.—Deep sleep resembling coma may be due to narcolepsy, a curious condition in which an uncontrollable desire to sleep recurs at irregular intervals. Subjects of this disease also are liable to sudden falls, without loss of consciousness, cataplectic attacks, which must be distinguished from petit mal. These attacks are brought on especially by the emotion of laughter, the legs giving way suddenly. Indeed, they remind us of the well-known saying of being 'helpless from laughing'. Bromide and luminal are of no use in this disease, but ephedrin may be tried. Similar overpowering sleep may be met with in acromegaly, and in other lesions near the pituitary infundibulum and floor of the third ventricle, an area of the brain which is especially associated with the phenomena of sleep. This association is also seen in encephalitis lethargica, in which the vascular lesions are particularly prone to affect this neighbourhood.

Coma may, of course, be due to many other poisons than alcohol. Nowadays the barbiturates, such as medinal or veronal, and luminal, are commonly taken in attempted suicide. Opium and morphine poisoning are less common since the Dangerous Drugs Act, except in medical men. If no signs of corrosion around the mouth and lips are evident, in the absence of signs of cerebral injury or hæmorrhage, or causes already discussed, washing out the stomach should be resorted to as soon as possible, using weak permanganate solution, if obtainable. Strong coffee should then be inserted through the tube, and hypodermic injections of ether, coramine, and camphor in oil.

The breath of a comatose patient may suggest alcoholism, or the heavy urinous odour of uræmia, or the sweetish odour of acetonaemia in diabetic coma. For uræmia, rectal injection of 25 per cent magnesium sulphate solution, and venesection of 15 oz. should be done, followed by the slow injection of half a pint of normal saline, followed by a smart purge.

In diabetic coma the immediate hypodermic injection of 30 units of insulin may restore consciousness, when a piece of cane sugar should be given, and blood-sugar estimations made. It must not be forgotten that coma may ensue in a diabetic patient due to hypoglycæmia, from excessive insulin dosage, especially if this is given shortly before heavy exertion, such as a game of cricket or football. This condition is usually preceded by irregular twitchings of the limbs. The blood-sugar is then much below normal, and the immediate intravenous injection of 20 c.c.m. of 30 per cent glucose solution should be administered, or, failing that, rectal injection of 4 oz. of 30 per cent glucose.

Hypoglycæmia may even occur without insulin treatment in cases of pancreatic tumour involving the Islands of Langerhans. These have been successfully removed by operation.

HEADACHE

Headache is one of the commonest symptoms calling for treatment, and its various causes are almost infinite in number. Yet, before administering aspirin, phenacetin, bromide, antikamnia, phenazone, or any of this range of painkillers, some rough attempt should be made to locate the cause. If it is one of a long series of headaches that have recurred at intervals for years, it is probably a case of migraine, especially if the headache is preceded by visual spectra of the well-known scintillating scotoma or fortification type, or the visual interference may be the sudden onset of hemianopia which will last perhaps 20 minutes. I have known the case of a hospital nurse who, when first attacked with this visual disturbance went to look at herself in a mirror, and being able to see only one half of her face became so frightened that she went off into hysterical convulsions. No headache

is present in this prodromal stage, but after an hour or so it may rapidly become violent and almost unbearable. An injection of 10 minims of 1 in 1000 adrenaline solution is sometimes very efficacious, but the ordinary headache remedies taken by the mouth are often useless, more particularly if vomiting starts early, as no remedy taken by the mouth can be retained. A hypodermic injection of grs. 3 of sodium luminal may then be given if the adrenaline has failed. In those cases in which vomiting does not start early, a cachet of grs. 7 of pyramidon with grs. 3 of cannabin tannate, grs. 1½ of sodium luminal and gr. ½th heroin is a useful combination to control the severity of the pain, sometimes aborting it within an hour in cases which otherwise are likely to continue for 12 hours or more. A heaped teaspoonful of effervescent litmopyrin (Bishop's) in a small wine-glassful of water taken immediately after the cachet is a useful addition.

Recurrent violent unilateral headaches may be due to other causes than migraine. One of the commonest and most important to recognize is sinus infection of the frontal sinus or of the antrum. Pain starting over the eyebrow about 10 or 11 a.m. and lasting until the late afternoon, day after day, is very suggestive of this cause, and the pain, especially in frontal sinusitis, may be so violent as to be almost unbearable. A small pledget of cotton-wool soaked in 20 per cent cocaine solution should be gently inserted and pressed against the lateral wall of the upper nasal cavity. This may arrest the pain almost like magic, and it acts by constricting the turgid mucous membrane and allowing drainage to take place from the sinus into the nose, thus relieving pressure. Do not forget the serious danger of a chloroform anæsthetic soon after using cocaine, as many deaths have been thus caused. Transillumination of the sinuses with a small but strong electric light in a darkened room will usually demonstrate a marked difference between a normal and an infected sinus or antrum, and the technique is so simple that every one of us should be familiar with it, and it should be used in every case of constant or recurrent headaches. X-ray pictures of the sinuses should also be taken when in doubt, and transillumination cannot reach the ethmoidal and sphenoidal sinuses.

Another form of recurrent unilateral violent pain in the eye and eyebrow is not associated with sinus infection, but may be a form of migrainous neuralgia. When limited to the region of the eyeball, I speak of it as *ciliary neuralgia*. The violence of the pain may be so intense as almost to drive sufferers to suicide, the pain lasting for one to two days, and recurring every few days for a period of weeks, and then perhaps disappearing for several months. Nasal douching with cocaine solution should be tried, as already described, and I have had several cases which have been completely cured by alcohol injection of the Gasserian ganglion. This type of neuralgia is quite different from that of the paroxysmal tic of *trigeminal neuralgia*. In the latter the paroxysms of pain last only for half a minute or so, but may recur every two or three minutes. I saw one such case a few weeks ago in August who had been sent home to me from Burma, who had had such violent shocks of facial pain on the right side every two minutes with very little sleep, since the beginning of June. Alcohol injection of the Gasserian ganglion arrested the pain instantly, but I cannot recommend this treatment to you for your own use in practice, as it is a very delicate method and requires long training to acquire the necessary dexterity.

Headache is likely to be a prominent symptom in the early stage of *meningitis*. There is probably some fever, and possibly delirium, and at first you may be doubtful of early typhoid. In the latter the abdominal reflexes are often absent and the typical rash may be seen, but do not be put off the diagnosis because the Widal serum reaction is negative during the first eight days. The spleen, too, may be palpable

and there is no head retraction, no rigidity of the neck muscles, nor Kernig's sign, as are likely in meningitis. The pupils in the latter may be conclusive, sluggish, perhaps unequal, and dilated, with an irregular pulse and vomiting. Lumbar puncture should be done, and the pressure noted on the manometer, if you have the necessary apparatus. The pressure is likely to be raised far above the usual 140 mm. Note if the fluid is clear or turbid. If clear, it may be a case of tuberculous meningitis, and examination of the fluid by a pathologist may demonstrate tubercle bacilli in the spider-web clot after standing, and the fluid is likely to contain diminished chlorides and a large excess of lymphocytes. Somewhat similar symptoms may occur in serous meningitis, but tubercle bacilli and lymphocytes are then absent and rapid cure is likely to occur and the withdrawal of 20-30 c.cm. of cerebrospinal fluid. If the fluid withdrawn is turbid the meningitis is likely to be of the cerebrospinal type due to the meningococcus, or it may be pneumococcal or even streptococcal. Stained films will distinguish between these forms, but in each case repeated daily lumbar puncture should be done, with the withdrawal of as much fluid as will flow readily, and then give an intrathecal injection of 20 c.cm. of anti-meningococcus serum. If the meningitis is secondary to mastoid disease, or following an operation on the nasal cavities, or fractured base, or cellulitis, then it is usually due to streptococcus infection, and the chances of saving your patient are very slight, though the cerebrospinal fluid should be drained by repeated lumbar puncture, twice daily, and hexamine administered by the mouth in grs. 20 doses t.d.s. in a tumblerful of water. Antistreptococcus serum is of probably doubtful value, though it may be tried.

Headache in cerebral tumour may be intense, calling for urgent relief. Lumbar puncture here is dangerous, because of the great risk of the increased pressure in the ventricles forcing the medulla and pons into the foramen magnum, with a fatal result. Morphia also is dangerous if there are signs of commencing torpor, but aspirin and phenacetin may be used safely. Certain relief may be obtained by puncturing the lateral ventricles, but this is an expert surgical procedure, and gives only temporary relief, unless followed by an extensive decompression.

Pyrexia of 101°-103°F. with cerebral symptoms of headache, torpor, and even delirium and coma may be the initial stage of an acute poliomyelitis, so that it is important to watch the muscular tonus of the limbs for the onset of a flaccid palsy. The deep reflexes will probably be lost, but sensation is unimpaired. The paralysis may spread widely during four or five days, though the ultimate permanent paralysis and muscular atrophy is usually much less in extent than is present in the first week. In young children there is often little or no pain, and in some cases the sudden onset of paralysis of a limb is the first symptom. In young children, too, scurvy rickets may simulate acute poliomyelitis on account of the muscular weakness, and I have known of a case in which the practitioner cured his little patient with potato and fresh milk after a leading neurologist had diagnosed infantile paralysis. Thus may too narrow a specialism defeat itself. Unfortunately little can be done either to avert poliomyelitis or to arrest the development of the spinal lesions and the subsequent muscular paralysis. Serum from a previous sufferer from the disease has been tried many times, apparently without any good effect. During an epidemic of the disease it will be wise to advise all communities, such as school-children, to have the throat and nose sprayed daily with a mild antiseptic. Acute poliomyelitis occasionally attacks adults, and it is then often an extremely painful disease for the first few days, usually being mistaken for neuritis, malaria, dengue, or influenza.

During epidemics of poliomyelitis there is often seen an increase in the number of cases of herpes zoster. This is probably also due to a filter-passer

virus, and it has a special relationship to the virus of varicella, innumerable cases of apparent infection of the one disease from the other being recorded. When zoster attacks the trunk, the onset of unilateral pain should give the clue, and it is wise to warn the patient that presently an eruption in the region of the pain is likely to occur, lest the rash when it appears is attributed to the treatment, and a change of doctor called for. Zoster is especially liable to affect the ophthalmic branch of the trigeminal nerve, and the pain may be agonizing. If the vesicles attack the cornea, severe scarring, perforation, and blindness may result, or iritis and even optic neuritis are met with. An ointment of zinc cream containing cocaine and chloral hydrate should be used for the painful rash, which should then be dusted over with boric powder and starch. Morphia may be necessary to give rest and sleep in severe cases, though this should not be continued for more than a few days owing to the danger of formation of an addiction habit. In old people *post-herpetic neuralgia* is exceedingly common and is very difficult to treat. Morphia should be avoided and reliance placed on milder sedatives such as bromide, and hypnotics, including allonal, adalin, and many others of this type, changing the drug every week. Operative treatment is useless, and alcohol injection is also as a rule useless in the spinal cases, though occasionally Gasserian injection is helpful in the trigeminal cases, when in addition to the pain there is troublesome hyperæsthesia.

Modern Methods of Treating Pulmonary Tuberculosis

By C. E. H. ANSON, M.B., B.S. (Lond.)

(Abstracted from the *Medical Press and Circular*, New Series, Vol. CXXXVI, 11th October, 1933, p. 339)

THE mortality from pulmonary tuberculosis in 1901 in England and Wales was 41,224, or 1,263 per million deaths, while in 1929 it had declined to 31,425, a standardized rate of 738 per million. A consideration of the modern methods of treatment in this disease which have contributed to this reduction in mortality may prove of some interest.

THE SANATORIUM

Although not a modern method of treating pulmonary tuberculosis, the sanatorium is worthy of special mention because of the great advances made in recent years in promoting a more happy and contented atmosphere among the inmates. In few other diseases is a peaceful and contented mind of such importance as in pulmonary tuberculosis, partly by reason of the long periods of institutional treatment necessary and partly because complete bodily rest is impossible in the presence of a fretting and discontented mind. The recognition of this fact has led to the provision in modern sanatoria of many social and occupational amenities which do much to reconcile the sufferers from this disease to long periods of institutional treatment with its inevitably monotonous daily routine. The beneficial effect produced by congenial occupation for mind and body on their health and progress while in the institution is surprising, and the knowledge gained from the instruction given is often turned to good financial effect after the patient has returned to his or her home.

The foregoing describes a few of the changes made in recent years which add to the patients' comforts and pleasures, and which have, by promoting a happy and contented atmosphere and combating introspection, enabled many to carry out the long periods of sanatorium treatment necessary to secure arrest of the disease in the more advanced type of case.

AFTER-CARE

The development of the highly organized and efficient system now in operation for the welfare or

supervision of a patient after leaving a sanatorium is a milestone in modern treatment. The facilities for the maintenance of artificial pneumothorax or oleothorax cases, and the placing of ex-sanatorium patients in suitable employment with a continuation of regular medical supervision at local dispensaries, are but a few of the items dealt with by this valuable public service.

Having now briefly reviewed the more important recent advances in the regime of sanatoria to which a sufferer from pulmonary tuberculosis must conform, we may consider some of the specialized forms of modern medical and surgical treatment for this disease, and in which such striking advances have been made.

Speaking broadly, the results of such treatments lie almost as much in the hands of the general practitioner as they do in those of the specialist who is responsible for the actual technique; for success depends very largely upon the early diagnosis of an active tuberculous lesion, and the onus of this falls most heavily upon the family doctor. In dealing with any suspicious case of phthisis, the knowledge must be kept constantly in mind that the clinical diagnosis of pulmonary tuberculosis depends on the presence of a symptom complex, such as general lassitude and malaise, loss of weight, cough and, later, associated sputum, with or without clinical signs in the lungs. A positive diagnosis is placed beyond all doubt if tubercle bacilli are found in the sputum (if necessary using the antiformin method on a twenty-four hours' collection), or an area of infiltration is shown by a good radiogram.

INJECTION THERAPY

Under this heading certain substances require mention notably preparations of calcium, and various gold preparations.

THE GOLD SALTS

Gold salts have a definite place of some importance in the modern treatment of pulmonary tuberculosis, and providing that suitable cases are selected and due care exercised in the administration of the drug excellent results may be obtained. The salts employed are numerous, and the following may be mentioned: allocrysine, lopion, krysolgan or supragol, triphal, solganal, solganol B, crysodal, crisalbine and sanocrysin, although only the two latter call for detailed mention. The gold content of these preparations varies from 33.7 per cent to 50.96 per cent.

Möllgaard was the first to obtain gold sodium thiosulphate in a pure state, and he gave it the name of sanocrysin. The original preparation introduced in 1924 by Möllgaard for the treatment of phthisis is the salt most widely used in this country, and the most noticeable effects of this preparation, when a course is given by the intravenous route, is the elimination of tubercle bacilli from the sputum, while fibrosis and healing are promoted in the diseased areas.

The use of sanocrysin is indicated in the following types of case:—(1) Early infiltration affecting one-third or more of both lungs, especially if associated with tubercle bacilli in the sputum. (2) In conjunction with artificial pneumothorax, thoracoplasty or other form of collapse therapy in cases where the uncollapsed lung shows signs of early disease while the contralateral lung is in such an advanced stage that some form of collapse therapy is essential. (3) Its use has also been advocated in cases of acute tuberculous pleurisy. Speaking broadly, cases showing active breaking down of lung tissue with advancing excavation are unsuitable for treatment with gold salts.

In those cases where disease in both lungs is moderately extensive, but excavation is present on one side only, it may be wise to give a course of sanocrysin, and if a favourable result is obtained, as judged by the improvement in clinical and radiographic findings, to proceed to collapse the excavated and

more extensively diseased lung by artificial pneumothorax or phrenic evulsion. If necessary this treatment may be combined with a second course of sanocrysin, or small doses (*e.g.*, 0.15 gram) may be given at weekly intervals for some months, and the patient, if afebrile, allowed to get up and take moderate exercise regularly.

The technique of sanocrysin administration is a simple one, the drug being given by the intravenous route. A gradually increasing dose given at weekly intervals is a simple and efficacious method, the drug being made up at the time of administration in warm freshly-distilled water to such a strength that each c.c. of solution contains 0.05 gram of the pure crystalline salt. Individual opinions differ widely regarding the exact dosages to be used, but the following amounts have been found in practice to give good results in most cases without causing any severe toxic reactions: 0.05 gram, 0.1 gram, 0.15 gram, 0.25 gram, 0.35 gram, 0.4 gram, 0.5 gram. This last dose will be reached, if no complications have arisen, by the seventh week of the course if injections are being given weekly as advised above. This dose is then injected each week until a total amount of six to seven grams has been given. This constitutes a complete course.

Some authorities have advocated using the drug in the same way as a vaccine and giving a slightly increased dose as soon as the pyrexia, if any, which has followed the preceding injection has subsided. The results obtained by this method do not appear to be appreciably better than those obtained by the simpler routine of an increasing weekly injection as already described. Whichever technique is used the patient should be kept in bed for the first few days after the injection, and a convenient method, if the routine of weekly injections is followed, is confinement to bed for the first four days after the administration of the drug and then a maximum of three hours up per diem during the next three days, at the end of which time another injection is given.

The urine should be carefully tested for albumen before the course is started and for four days after each administration, while a sharp watch is kept for the appearance of any toxic phenomena. The toxic phenomena which may occur during the course of sanocrysin are numerous, but seldom serious, fatal reactions being extremely rare. The treatment of toxic symptoms is chiefly symptomatic, while the elimination of the drug by other channels is encouraged, *e.g.*, purgation, diuresis and sweating. The results of this treatment, providing that care is taken in the selection of suitable cases, are encouraging, and in a recent survey of a series of one hundred consecutive cases treated by sanocrysin nearly 50 per cent showed clinical improvement, together with the disappearance of tubercle bacilli from the sputum.

COLLAPSE THERAPY

The greatest advances in treatment of recent years have, however, been chiefly concerned with various forms of collapse therapy, and this valuable method must next be considered in all its aspects. It is wise to bear in mind that all procedures discussed under this heading should be regarded as surgical operations, and due attention paid to securing an efficient aseptic technique.

ARTIFICIAL PNEUMOTHORAX

In order to secure good results with this form of treatment the careful selection of suitable cases is of prime importance, and it is in this direction, coupled with the perfection of a rigidly aseptic or antiseptic technique and recognition of the importance of regular radiographic examination, that the greatest advances have been made in recent times.

Briefly, the cases in which unilateral artificial pneumothorax is indicated may be classified as follows:—(1) Moderately advanced unilateral disease in an active state, with or without excavation. (2) As in

(1), but with early disease affecting the apex or middle zone of the contralateral lung, in which case the treatment is advantageously combined with a course of sanocrysin, although in some of these cases collapse of the more affected lung is followed by clearance of disease on the opposite side. (3) In actively advancing bronchio-pneumonic and caseous pneumonic types, if unilateral. (4) In severe hæmoptysis in which the site of bleeding can be accurately localized. (5) For the relief of pain in pleurisy. (6) Certain cases of tuberculous pleural effusion and empyema. (7) Cases of laryngeal involvement in which pneumothorax appears suitable on other grounds should be induced at an early stage. (8) In those cases where the social or economic conditions of the patient render prolonged institutional treatment undesirable, and the case is suitable on clinical grounds.

Certain conditions may contraindicate artificial pneumothorax treatment, notably advanced asthma and emphysema, renal disease of an advanced degree (not tuberculous in nature), and advanced intestinal tuberculosis. The technique of artificial pneumothorax is too well known to require detailed description, but it cannot be urged too strongly that all aseptic and antiseptic precautions must be taken to prevent any risk of infection of the pleural space during the stage of induction or subsequent refills. Careful anaesthetization of the parietal pleura is important in avoiding the risk of pleural shock, and in this connection an injection of atropine (gr. 1/100) is of value if given about half an hour before the induction or refill is attempted, while in the former case it may with advantage be combined with morphia (gr. 1/2).

Air should never be introduced so rapidly as to cause any marked swing or displacement to occur in the mediastinum, and the amount given should be regulated so as to secure as good and complete a pulmonary collapse as possible without occasioning any cardiac displacement or throwing an undue strain on the contralateral lung. In this connection the importance of regular screening under the x-rays, if possible before and after each refill, cannot be over emphasized, and a sharp watch must also be kept on the condition of the contralateral lung. Adhesions which prevent adequate collapse of the lung or of an underlying cavity should, if practicable, be divided (*vide infra*).

The complications attending pneumothorax inductions or refills are: pleural shock, gas embolism, surgical emphysema, perforation of the lung, and cardiac accidents such as syncope or cardiac puncture. All these are of relatively rare occurrence. In all those cases where a full artificial pneumothorax is indicated and possible, the degree of collapse attained should be as complete as possible, but gross cardiac or mediastinal displacement must be avoided.

Complete collapse is desirable, as it secures the maximum rest for the diseased lung with resultant healing, the evacuation of the liquid tuberculous contents (as sputum), and reduces the risk of pulmonary rupture from coughing or straining. It also tends to reduce the liability to auto-inoculation, with resultant activation of tuberculous foci in other parts of the lungs, and spread of disease, which sometimes follows refills on an incompletely collapsed lung. As already stated, the optimum degree of collapse for any individual case can only be ascertained by careful and frequent x-ray examinations.

It is impossible to give any definite rule regarding the length of time an artificial pneumothorax should be maintained, the period varying from two to six or more years, and it should be decided for each individual case after careful consideration of the presence or absence of activity, the degree of disease present in the lung prior to the induction of the pneumothorax, and the social and economic status of the patient.

THORACOSCOPY AND DIVISION OF ADHESIONS

In some cases of artificial pneumothorax it is found impossible to obtain a good collapse owing to adhesions

which prevent the lung being compressed to the optimum degree by holding it tethered to the chest wall.

If the adhesions are situated over a cavity in the lung they may prevent its obliteration by the pneumothorax. In all such cases the possibility of securing a good collapse by dividing the adhesions should be considered, for as has been already pointed out, the maximum degree of collapse which can be obtained without causing cardiac or mediastinal displacement, or unduly straining the opposite lung, is the optimum if a satisfactory healing of the disease is to be obtained.

OPEN INTRAPLEURAL PNEUMOLYSIS

In those cases where owing to the size, position, density or number of the bands to be divided cauterization is impracticable, the pleural cavity may be opened under a general anaesthetic. Access is usually obtained through an intercostal space, and the adhesion divided. This method has the advantage that hæmorrhage is easily controlled, but the risk of infecting the pleural cavity is increased with liability to serous effusions, and even empyema. In some cases, however, excellent results have been obtained.

OLEOTHORAX

The oil used consists of liquid paraffin or olive oil containing oil of gomenol to the extent of 2 per cent to 6 per cent according to the type of case, the higher strengths being used in those where an antiseptic action is required. For all general purposes oil containing 2 per cent of gomenol oil is used. The indications for oleothorax are: (1) Pleurisy complicating pneumothorax; (2) obliterative pneumothorax or incomplete collapse of the lung or an underlying cavity; (3) mediastinal laxity combined with exaggerated pleural elasticity; (4) as a substitute for pneumothorax; (5) pleuro-pulmonary perforations.

The general technique adopted is as follows:—In all cases as complete an artificial pneumothorax as possible should be established before the introduction of oil. A preliminary injection of two to five cubic centimetres of oil should be given to test the susceptibility of the patient. If no intolerance is observed, 25, 50, 100 and then 300 to 500 c.c. may be given, allowing an interval of a few days between each injection, until the air in the pneumothorax space has been completely replaced with oil. If any reaction is observed advance must be made slowly. While the oil is being injected through a needle inserted into one of the lower intercostal spaces the air in the pneumothorax is sucked out through another needle at the apex by reversal of the bottles of the pneumothorax apparatus. The intrapleural pressure is adjusted at the end of each operation to a mean of zero. The oil should be run in at body temperature through a short needle with a bore of 1 to 1½ mm. For the injection of the larger quantities of oil a Dieulafoy's two-way syringe of 100 cubic centimetre capacity, or one of the special oleothorax apparatuses now on the market, may be employed.

If the oleothorax is being given for a tuberculous pleurisy the injections should not be made during the acute stage, while if a serous effusion is present the introduction of oil should be preceded by a gas replacement.

If the patient is being treated for a purulent effusion preliminary gas replacement followed by a pleural wash-out with some mild antiseptic, e.g., 1 in 4,000 acriflavine solution, should be the method of choice. The wash-outs may with benefit be repeated five or six times, with about five-day intervals, before the oil is introduced. In these cases paraffin containing 5 per cent to 10 per cent of gomenol has been advocated, but the risks of complications due to the latter are correspondingly increased.

Where obliterative process in an artificial pneumothorax indicate oleothorax treatment, any adhesions which can be divided should be dealt with before oil

is introduced, for the more complete the initial pulmonary collapse, the better the results of the oleothorax will be. The results of filling the various loculi in loculated pneumothorax cases have been most disappointing, and this procedure is not to be recommended.

In cases where exaggerated pleural elasticity with resultant instability of the pneumothorax is associated with mediastinal laxity, which precludes large refills being given owing to cardiac displacement occurring, the introduction of about 40 to 50 c.c. of 2 per cent gomenol by small amounts gives excellent results. In cases of pneumothorax where the patient will experience difficulty in obtaining refills after leaving the sanatorium (e.g., prospective emigrants), an oleothorax may be substituted. The use of gomenol for promoting closure of a pleuro-bronchial fistula is rather a questionable procedure, although some encouraging results have been reported.

The after-care of oleothorax patients is a matter of the first importance. Careful routine x-rays, clinical examinations, and periodic observations of the intrapleural oil pressure, and the giving of small refills should this begin to fall, are essential. Should fluid develop under the oil it should, if serous, be removed and replaced by more gomenol, while if found to be purulent on more than one occasion after replacement the pleural cavity should be drained of oil and pleural wash-outs given at intervals until the space is sterile. The oleothorax may then be re-established or a gelatinothorax (*vide infra*) contemplated. Various complications and accidents may be met with in the course of oleothorax treatment.

Initial fever varying from 99° to 104°F. may occur, accompanied by pain owing to pleural irritation by the oil. In the later stages of the treatment pyrexia may be due to the formation of fluid under the oil. Nephritis has been recorded, and this is possibly due to excretion of gomenol by the renal tubules in excessive quantities.

Perforation of the lung may occur if, owing to the formation of fluid beneath the oil, the intrapleural pressure is raised to a point where rupture into the pulmonary tissues takes place. This will only occur if clinical signs are ignored and careful x-rays and the general after-care of the case are neglected. More rarely perforations owing to renewed activity of the disease in areas lying under the visceral pleural surface may occur. In such cases evacuation of the oil and performance of a thoracoplasty is indicated, if possible on general considerations. In this connection it cannot be urged too strongly that no case in which the contralateral lung is not free of any appreciable degree of active disease should be treated by oleothorax. The method is, however, a very valuable complement of artificial pneumothorax if it is used with due care and judgment. The recent progress in the surgical treatment of pulmonary tuberculosis and complications of artificial pneumothorax has caused many of the indications for oleothorax which, other means lacking, were thought to be proper a few years ago to be abandoned.

In certain cases oleothorax has proved a failure, chiefly as a treatment for infected pleural effusions, and the method of gelatinothorax has been introduced in an attempt to improve the results. The medium consists of a sterile solution of 5 per cent of gelatin in normal saline with the addition of acriflavine to a strength of 1 in 2,000. The pH of the whole solution is adjusted to eight, and the solution sterilized and put up in ampoules.

SURGICAL MEASURES

We may now turn to the consideration of the surgical treatment of pulmonary tuberculosis, which is a natural corollary of artificial pneumothorax, although its advent actually preceded that of the latter by quite a definite interval, the resection of ribs with a view to obtaining some degree of pulmonary collapse being carried out by de Cernville as early as 1835.

The indications and contraindications for surgical interference are similar to those of artificial pneumothorax, but demand a much stricter interpretation of the case, especially as regards the activity of the disease, if any, in the contralateral lung. Brauer sums up the essential points excellently in the form of four questions, namely: (1) Can the patient recover without operation? (2) Will the contralateral lung stand the operation? (3) Is the pleura adherent? Test it. (4) Is the general condition of the patient and the state of the other organs good enough? With these preliminary remarks, and the reminder that the careful selection of suitable cases is of prime importance if good results are to be obtained, the individual surgical operations may be considered in detail.

OPERATIONS ON THE PHRENIC NERVE

The excellent results following operations on this nerve, coupled with the minor nature of the operation itself and the absence of any necessity for a general anæsthetic, have deservedly popularized these operations in selected cases. The object of the treatment is to give rest to the diseased lung, and this may be temporary or permanent, according to the technique adopted. Temporary paralysis of the diaphragm may be secured by either of the following methods: (1) crushing the phrenic nerve in the neck; (2) injection of alcohol into the nerve; while permanent paralysis of the muscle is secured by (1) phrenic evulsion; (2) phrenicotomy (it should be noted that in the small percentage of cases regeneration of the nerve may occur after division only of the main trunk, with recovery of function), provided that in each of the latter operations any accessory phrenic nerve is looked for and, if present, divided.

The indications for operation on the phrenic nerve may be broadly summarized as follows: (1) Failure to induce an artificial pneumothorax. (2) In pneumothorax cases where adhesions are causing trouble by traction, and cannot be dealt with by cauterization or other methods. (3) In artificial pneumothorax cases in which obliteration is beginning or has occurred. (4) In artificial pneumothorax cases which are being abandoned: (a) after more than two years; (b) where excavation is or was present; (c) where an abnormally complete pneumothorax is to be allowed to re-expand. (5) As an invariable preliminary to complete thoracoplasty. (6) In cases with bilateral disease where a bilateral selective pneumothorax cannot be obtained on more than one side. (7) Where artificial pneumothorax is contraindicated owing to heart disease or bronchitis. (8) Where the mentality of the patient is in doubt, or pneumothorax is refused in an otherwise suitable case. (9) As an adjunct to an artificial pneumothorax where only a partial degree of collapse can be obtained; but this has given a good functional result. (10) In certain cases with purely basal disease, with or without excavation, the method may be used instead of an artificial pneumothorax. (11) The relief of troublesome symptoms, notably cough, vomiting or hiccough.

The indications for the temporary or permanent operation are similar, but in the former advanced and active disease in the contralateral lung renders a permanent phrenic, with the permanent increase in the strain on that organ, undesirable. The former is also indicated where the disease is so slight that a permanent paralysis of the diaphragm on the affected side appears undesirable. In some cases where bilateral disease is present and it is impossible to induce a pneumothorax on either side, a bilateral crushing of the phrenic nerve may be of value. About three weeks should elapse between the two operations.

The operative technique employed is simple. The phrenic nerve is exposed under local anæsthesia as it lies on the anterior surface of the scalenus anticus muscle. If a permanent paralysis of the diaphragm is desired about three to seven inches are evulsed, or if this is impracticable the main trunk is divided, while if a temporary result is required about a third of an inch of the main trunk is crushed, but not

actually divided. In all cases any accessory branches should be looked for and divided. In locating the main nerve trunk or the accessory branches the illuminating retractors devised by H. P. Nelson will be found of great assistance. If the nerve is crushed and not evulsed it is a good plan to tie a loop of sterilized black silk loosely round the main trunk. This greatly facilitates finding the nerve again should a permanent operation become desirable at a subsequent time. The complications following operation on the phrenic are negligible beyond occasional local sepsis. In those cases where a temporary operation has been done recovery of the diaphragmatic movements occurs about six months later. The degree of change noticed in the diaphragmatic movements after a successful operation, when the patient is examined under the x-rays, varies from immobility with no rise in level to a rise of three or more inches with marked paradoxical movement.

THORACOPLASTY

In considering the question of thoracoplasty it should be emphasized at the beginning that the operation is a serious one, causing considerable mutilation not only to the patient's body but for a time at least to his psychology and mental balance. Moreover, extreme care must be taken in the selection of cases for this method of treatment, and any case showing more than a limited amount of quiescent or arrested disease in the contralateral lung is, broadly speaking, unsuitable for this operation owing to its irrevocable nature and the risk of extension in the opposite lung which often follows the rapid compression of the more diseased side. The preliminary phrenic evulsion which should precede any operation for complete thoracoplasty is of great value by acting as a test for the quiescence or otherwise of the disease, if any, in the opposite lung. The operation should not be done in any patient over forty-five years of age, and is contraindicated in all exudative cases.

Other surgical procedures that have been advocated and that are suitable in certain cases are scalenectomy, intercostal neurectomy, pneumolysis and pneumonotomy.

SUMMARY

(1) An attempt is made to present the results of personal experience and the general consensus of opinion on various modern methods of treating pulmonary tuberculosis. (2) The importance of an early diagnosis is emphasized. (3) The indications for technique of, and complications following, various treatments are discussed.

The Therapeutics of Malaria

THIRD GENERAL REPORT OF THE MALARIA COMMISSION
(Abstracted from the *Quarterly Bulletin of the Health Organization of the League of Nations*, June 1933, Vol. II, No. 2)

GENERAL AIMS

1. It has always been common knowledge that a large proportion of those who suffer from malaria in poverty-stricken countries never get any specific treatment for their disease. The League of Nations' Malaria Commission, when it was created in 1923, decided to collect information on the subject and to endeavour to discover how it might be possible to provide treatment for those victims. At that time, of course, 'treatment' was synonymous with 'quinine' (for no other specific was available), and the problem was therefore how to provide those people with quinine. It was realized that the cost of quinine itself was only one among many reasons why the people lived and died without the drug; but it was thought that, if by some means or other, a world reduction in the price of quinine could be brought about, something at least would have been accomplished.

2. In starting out with this aim (how to reduce the price of quinine) the Commission was embarking on

an economic rather than on a medical problem, but there was one way in which it could be approached from the medical side. Perhaps it might not be necessary after all to employ pure quinine. Perhaps one or more of the other alkaloids in cinchona bark might be sufficiently effective, as shown by the large experience in India; or perhaps a mixture of all the alkaloids in a cheaper species of bark than that used commercially for the extraction of quinine might serve.

3. The Commission collected all available information on these and related subjects and a great deal of research on total alkaloids and alkaloid mixtures was undertaken under its auspices. The position was then fully discussed at two conferences held in London and Geneva. As a result, it was decided to suggest the preparation of a new cinchona product to be called 'Totaquina'. This product was to be a mixture of all the alkaloids in cinchona bark standardized to contain not less than 70 per cent of the crystallizable alkaloids, of which not less than 15 per cent must be quinine, with not more than 5 per cent of moisture and 5 per cent of mineral matter. In actual commercial practice, two types of preparation complying with this specification can be made—namely: *Type I*, made by extracting and precipitating as an almost white powder the total alkaloids from the bark of *C. succirubra* or *C. robusta*, which can be cultivated abundantly in almost every malarious country; *Type II*, made by utilizing the residues remaining after quinine sulphate has been extracted from *C. ledgeriana* and bringing the preparation up to the required standard by adding sufficient quinine and other crystallizable alkaloids.

4. Samples of the two types were obtained and were analysed independently by Dr. Groothoff and Dr. Henry and tested for their antimalarial activity on bird malaria by Professor Giemsa. These three experts then drew up a scheme for the specification of totaquina and for its analytical control, which, on the recommendation of the Health Committee, was forwarded to committees responsible for the issue of national pharmacopœias with a view to the insertion of the new preparation in those publications. This has been done in the new edition of the British Pharmacopœia issued in 1932.

5. On the medical side of the problem, the next task was to supplement Professor Giemsa's study of the antimalarial activity of totaquina in bird malaria by clinical investigations of its remedial action on cases of the disease in man. This enquiry has been commenced, but the trials reported are as yet too few to enable the Commission to make definite recommendations on dosage, mode of administration and other details.

6. While this work was proceeding, two events of outstanding importance in the history of malaria research occurred. The first was the late Dr. Roehl's routine application on a large scale of a method which he had devised for seeking antimalarial remedies by testing numerous quinine and quinolin derivatives to ascertain whether any of them were effective against the parasites of bird malaria. The second was the application of the practice of malaria therapy to the study of malaria itself as well as for its original purpose. These events quickly led to great advances in knowledge on both the chemical and biological aspects of malaria and to a change of thought and opinion on the aims and methods of antimalarial treatment and prevention.

7. On the chemical side, an epoch-making advance was the discovery of synthetic preparations which give promise of being more effective therapeutic and prophylactic agents than quinine.

On the biological side, additions to knowledge have been no less important, although they may appear less spectacular. For example, as regards quinine, its merits and defects as an antimalarial agent have been, for the first time, clearly defined and described. It has been shown that, although quinine suffices in large

measure to satisfy the practising physician by virtue of its action on the asexual stages of the parasite which are responsible for the fever and other clinical symptoms of malaria, it has three grave defects from the point of view of preventive medicine. It does not destroy the sporozoite stage of the parasite, which is responsible for infection; it has only a slight action on the sexual stage, which is destined to continue the life cycle of the parasite in the mosquito, and its curative effect is not always permanent, for the disease is liable to recur within a short or a long period after cessation of treatment. It has been shown, further, that, even as regards the use of quinine by the practising physician for the cure of malarial attacks, the time has passed when it can be considered satisfactory or sufficient to make a diagnosis of 'malaria' and to begin at once a 'standard quinine treatment'. Nor is it sufficient to know the species of parasite concerned and to prescribe the particular system of quinine treatment which, up to now, has been considered most appropriate for an infection of that type. What has to be done now is to endeavour to learn much more about the case than has been customary hitherto. It has become all important to know what is, in general, the clinical virulence of the particular strain of the parasite with which the patient is infected, what is the usual course of the disease in treated and untreated infections with that strain, and what is the patient's status as regards tolerance or immunity to its clinical effects. For, to existing knowledge that some species of the malaria parasite are much more virulent to the human host than others has been added the information that there is a difference between the clinical virulence of different geographical races or strains of the same morphological species. This finding has an important bearing on treatment. It serves to explain contradictory observations on the therapeutic efficacy of the same form of treatment conducted in different countries and on the comparative value of different systems of quinine administration, as well as divergent views on the relative amenability to quinine treatment of the different species of the malaria parasite. Also, to existing knowledge that persons who suffer repeatedly from malaria gradually acquire a tolerance or immunity to the disease has been added the information that this tolerance is specific to the particular species and strain of parasite concerned and that by too intensive or too early treatment with quinine the patient may be prevented from acquiring that tolerance and so may continue to suffer for a very long period from the relapses which are such a troublesome and debilitating feature of malarial fever. Again, as regards the common practice of taking a 'prophylactic' dose of quinine daily, the manner in which this dose acts (by mitigating or suppressing the clinical symptoms rather than by preventing infection) has been ascertained and defined so clearly that there is no longer doubt or confusion on the matter, and no longer any reason for advocating or for condemning the practice in all circumstances, or for inability to define the conditions in which the practice should still be advised and the period over which the doses should be taken. Thus, in the prophylactic as well as in the therapeutic sphere, the new knowledge obtained about the action of quinine, while it increases the responsibilities of physicians and public health workers, should enhance greatly the benefits which the discovery of this natural product has already conferred on millions of people.

8. And, of course, this new knowledge about quinine is not rendered unnecessary, nor is its practical utility lessened, by the discovery of synthetic drugs which may in some respects be more effective antimalarial agents. For, in practical antimalarial work on a large scale (which is the work with which the Malaria Commission is primarily concerned), the question of competition between the old remedies and the new does not arise. The aim of large scale antimalarial effort by means of drugs is not concerned with providing a medicine which is the most effective antimalarial

remedy known to medical science. What is aimed at is to provide a remedy that is so abundant and can be obtained so cheaply that it can be made readily available to the whole population of malarious countries. The endeavour of the Malaria Commission is to arrange a scheme of that kind. In such a plan there is no question of providing the most effective remedy known, nor even, necessarily, of providing a remedy as effective as quinine. The object is simply to provide, preferably by local cultivation of *C. succirubra*, or by other action in the malarious countries themselves, an abundant supply of a medicine which will mitigate the severity of malarial attacks and prevent the disease from terminating fatally. This, of course, is a limited aim, but it is often all that can be hoped for in the numerous poverty-stricken localities where malaria prevails. Moreover, a therapeutic policy designed to reduce the severity and fatality of the disease rather than to eliminate the parasites radically and completely is one that, in existing circumstances in some severely affected countries, can be justified on scientific grounds. It is known, for example, that in some localities in Africa and other tropical countries, the entire native population above one year of age harbour malaria parasites in their blood continuously, although no one above a few years of age suffers any appreciable illness attributable to the parasitic infestation. The latter result is due—as has been proved by laboratory investigations made in connection with the practice of malaria therapy—to the fact that many persons who are repeatedly infected and reinfected with malaria quickly become immune to the clinical effects of the infecting organisms although the parasites themselves survive and continue their life cycle in the human host. This condition of acquired immunity resulting in freedom from malarial disease after childhood is advantageous to the populations concerned, and radical interference with the process by which it comes about might be most unwise. Evidently, what is needed in localities of that kind is intensive systematic enquiry into the clinical aspect of the subject for the purpose of ascertaining precisely at what period of life temporary curative measures are urgently necessary or would be most helpful. It might well be that the best interests of the indigenous inhabitants of these countries would be served by providing them with a remedy such as totaquina rather than with one which, by its more potent curative or protective action, would prevent them from acquiring during infancy and early childhood the immunity of the disease which is so valuable during the working years of life.

9. At the same time, of course, the Commission appreciates fully the great benefits that would be derived from the power to fight malaria with more drugs than the cinchona alkaloids and especially from the ability to fight it with preparations which may be effective for particular purposes for which quinine is known to fail. Although quinine is one of the most remarkable drugs in the world, it has to be admitted that, as an antimalarial agent, it has several grave defects which are the more apparent when attempts are made to utilize the drug for preventive work on a large scale. It is common knowledge that after the discovery of the mosquito cycle of the malaria parasite, several workers believed that the best hope of overcoming malaria on a large scale lay in an endeavour to break the epidemiological chain by treating the human host rather than by measures aiming at the destruction of the insect carrier. That view has since received support from the success which has attended medicinal measures against kala-azar and bilharziasis, but, as regards malaria, field experiments on a similar plan have always failed because taking quinine, although it cures developed attacks, does not always prevent either man or mosquito from becoming infected. It is reasonable to suppose that, if a drug possessing that property were available, a repetition of Koch's field trials might have a very different result.

Whilst the original object of enquiry by the Commission was the treatment of poor populations by quinine, it is impossible to overlook the importance of the treatment of malaria in general, whether of the individual or of communities and under all conditions. Here also the discovery of new drugs which are more effective for particular purposes than quinine has a very great value.

The above are the principal justifications for chemotherapeutic research and experiment.

Mixtures of cinchona alkaloids

The Commission, assisted by an expert committee, which included Sir Henry Dale, Sir David Prain, Mr. Howard, Mr. Blagden, Dr. Henry and Dr. Wenyon, has endeavoured to disentangle the confusion which exists with regard to the names and composition of mixtures of the cinchona alkaloids commonly used as antimalarial remedies. Their conclusions, briefly stated, are :—

(a) The name 'quinetum' should be reserved for a preparation consisting of quinine, cinchonidine and cinchonine in equal parts. If this preparation were made by extracting those alkaloids from the bark of *Cinchona succirubra* (which usually contains them in approximately equal quantities), only a small addition of one or other of the crystallizable alkaloids would be necessary in order to equalize the amount of each alkaloid in the preparation.

(b) Instead of continuing to use the name 'cinchona febrifuge', which in the past has been applied to alkaloidal mixtures of very different composition, it is suggested that a new *standardized* preparation containing all the alkaloids in cinchona bark should be recommended for general use in treating malarial populations, and that its name should replace the name 'cinchona febrifuge'. The new preparation should be standardized to contain not less than 70 per cent of crystalline alkaloids, of which not less than 15 per cent must be quinine. The amount of amorphous alkaloids must not exceed 20 per cent, mineral matter not more than 5 per cent and water not more than 5 per cent. The name suggested for this new preparation is 'totaquina'. Here all that is required is a record of the few preliminary clinical tests which have been made with the preparation and a recommendation that it should be tried in the field on a large scale. The composition (approximately) of available samples of the two types of totaquina is as follows :—

	Type I, made by extracting the total alkaloids from cinchona bark		Type II, made by adding to the residues of quinine manufacture sufficient alkaloids to bring the preparation up to the required standard
	<i>C. succirubra</i>	<i>C. robusta</i>	
	Per cent	Per cent	Per cent
Quinine ..	25.23	28.46	14.79
Cinchonine ..	27.67	16.00	55.11
Cinchonidine ..	34.13	47.53	7.10
Quinidine	6.21
Total crystallizable alkaloids.	87.03	92.0	84.2
Amorphous alkaloids.	8.86	3.70	10.47
Moisture ..	0.99	1.00	1.77
Ash ..	0.63	1.67	2.13

It will be seen that, while the alkaloids in type I are chiefly quinine and cinchonidine, the chief alkaloid in type II is cinchonine. Also, type II contains quinidine, which is not present in type I and it contains a larger amount of amorphous alkaloids.

On account of their different alkaloidal contents, the therapeutic properties of types I and II must be considered separately.

Results of tests on bird malaria

Professor Giemsa has made toxicity and therapeutic tests of samples of each type in comparison with quinine and hydroquinine by the method of Roehl. The results showed that all the samples tested (three of type I, one of type II) were a little more toxic when injected intravenously into rabbits than hydrochlorate of quinine administered in the same doses, and that, as regards their therapeutic action on the parasites of bird malaria (*P. relictum*), all of them were inferior to quinine. The sample which contained the largest amount of quinine (a preparation of type I containing the total alkaloids of *C. robusta*) was the most active therapeutically, and the two samples of type I containing the total alkaloids of *C. succirubra* came next. The sample of type II made from the residues of quinine manufacture and which contained less quinine but more cinchonine than any of the others was found to be least effective therapeutically. Professor Giemsa concluded that the therapeutic action of the preparations was directly proportional to the amount of quinine which they contained.

Results of tests on human malaria

Tests on benign tertian malaria, *P. vivax*, intentionally induced by the bites of mosquitoes.

The results are very much the same as those obtained by Professor Giemsa in tests on bird malaria. They may be summarized as follows :—

(1) One dose of 5 grains (0.3 gm.) of totaquina of either type has practically no effect on the fever or parasites. It is necessary therefore to use a single dose of 10 grains (0.6 gm.) for the test.

(2) A single dose of 10 grains of totaquina type I produces the same effect in aborting the fever and in reducing the parasites as is produced by a single dose of 5 grains of quinine.

(3) A single dose of 10 grains of totaquina type II has practically no effect in aborting the fever or in reducing the parasites. With this type of totaquina it is necessary to use a single dose of 20 grains (1.2 gm.) to produce the same effect as is produced by a single dose of 5 grains of quinine.

It appears from these results that totaquina type I (total alkaloids of *C. succirubra* or *C. robusta*), when used in ordinary clinical therapeutic doses for curative purposes—e.g., 12 gm. (20 grains) daily for five to seven days—should give about the same good result as is given by quinine in the same doses. If this is so, and if this type of totaquina can be obtained more cheaply than quinine, it would be advantageous to use it for general purposes instead of the single alkaloid.

The following is the method suggested by the Commission for further clinical trials of totaquina:

Procedure

(a) The drug should be administered by the mouth daily in a dose of 0.60 gm. (10 grains) for benign tertian, 1.20 gm. (20 grains) for malignant tertian or quartan. The medicament should be given in tablet form.

(b) Only patients with acute clinical forms of malaria and schizonts circulating in the blood to be treated. The dose should be given under the direct supervision of the doctor.

(c) Continue the treatment of cases by the drug under test or by quinine controlled by daily blood examination until five doses have been taken (five days).

(d) Note carefully and secondary effects, *c.g.*, nausea, albuminuria, etc.

(e) Comparison will be made of the lapse of time required for the complete disappearance of the schizonts from the blood according to a thorough study of the preparations. The blood examinations should be carried out by the same person using the same technique throughout the whole duration of the experiment.

(f) It is desirable to make the experiment on at least fifty patients treated with quinine and on fifty treated with totaquina for each of the three species of parasite. Selection of cases should be made in order that, as far as may be practicable, each group will contain an equal number of cases of the same age and sex in the same stage of the disease.

(g) The description of the dosage, symptoms and results must be written on the special forms provided by the Health Organization of the League of Nations.

(h) The nature of the attack should be determined as accurately as possible. It is desirable, in particular, to know if it is a primary attack or a relapse and for how many days the patient has had fever before the first day of treatment.

Dysphagia

By STANFORD CADE

(From the *Lancet*, 4th November, 1933, Vol. II, p. 1058)

I AM concerned in this lecture with some practical considerations of the common conditions producing dysphagia. From an academic point of view it is no doubt interesting to argue whether some case of difficulty in swallowing is due to spasm of a sphincter or to failure of relaxation of the same sphincter; from the practical point of view it matters chiefly to discover whether the difficulty in swallowing is due to a malignant growth or to some other cause. The only way of differentiating the various cases is by submitting them all to a complete investigation at the earliest possible moment. Age, sex, mode of onset should not be used as an excuse to postpone investigation. In cases of dysphagia there is no justification for 'expectant' treatment. The erroneous impression gained from the literature that dysphagia is not uncommonly due to spasm, aneurysm, cicatricial contraction, or diverticula is due to the fact that such cases are often reported, being interesting and presenting some special feature. In reality they do not account for more than 6 to 8 per cent of all cases, the vast majority being due to a malignant growth. This being the case it is of the greatest importance not to delay diagnosis.

A systematic investigation should consist of the following steps:—

1. *History of the case.*—This should be taken in detail; it will throw a great deal of light on the case. Direct inquiry should be made for trauma, foreign bodies, burns. A statement by the patient that dysphagia has been present for years, that it is intermittent, that it occurred often under emotional strain or with certain foods only should not be allowed to detract attention from the graver possibilities and must not encourage the practitioner to prescribe belladonna and hope for the best. It must be remembered that a long history of slight or intermittent dysphagia does not infrequently precede the development of a neoplasm and that the 'text-book picture' of fairly rapid and relentlessly progressive difficulty in swallowing is not always obtained. With equal caution must be received the statement that dysphagia occurred as 'a bolt from the blue' in the middle of a meal and the first indication was sudden but complete and temporary inability

to swallow. Direct inquiry should be made about: (a) vomiting, its quality, quantity, and relation to swallowing; (b) increased salivation and presence of mucus in the throat; (c) occasional streaks of blood in the sputum; (d) change of voice, however slight.

A carefully obtained history often helps to establish a diagnosis of the rarer causes of dysphagia, but it must never be forgotten that by far the commonest cause is a malignant growth somewhere between the pharynx and the cardia and deliberate search is to be made for it.

2. *Clinical examination* should consist in a systematic examination of the mouth, pharynx, and larynx. The lateral walls of the pharynx, the pyriform fossa, and upper aperture of the larynx should be scrutinized. A pool of mucus behind the arytenoids, or frothy saliva in one pyriform fossa should arouse the gravest suspicion. The presence of cedema or an ulcer make the diagnosis nearly a certainty. A routine examination of the neck, chest, and abdomen should always follow. And lastly, the patient should be given a tumbler of water and swallowing observed.

The accidental discovery of an unsuspected lesion elsewhere should not deter one from a complete examination. The greatest injustice to the patient is a diagnosis of 'functional' dysphagia without the fullest possible examination.

3. *X-ray examination* should consist of: (a) A preliminary skiagraphy of the chest with special attention to the mediastinum. (b) Screening of the œsophagus with an opaque meal of fluid, semi-solid and thick barium. The clinician interested in the welfare of his patient will be present at this examination. The meal should be visualized from the mouth down to the stomach both in the antero-posterior and oblique positions. (c) Films should be taken as they may reveal beyond the actual narrowing of the lumen of the œsophagus, extramural extension of the disease, its size and position.

4. *Œsophagoscopy.*—In careful hands this is a minor procedure. It should never be omitted; it should follow and not precede x-ray examination, and it can give details of the type, size, and extent of the lesion unobtainable by other methods of examination.

The three following points require emphasis: (a) Bougies are dangerous and of doubtful usefulness, and should never be used unless under direct vision through the œsophagoscope. (b) A positive Wassermann reaction does not signify that the patient is free from all other diseases and time must not be wasted in protracted antisyphilitic treatment. (c) A negative result of a biopsy is of little value and should not outweigh clinical evidence.

Success or failure of treatment depends upon early diagnosis. If the lesion is benign, appropriate surgical treatment gives satisfactory results. Early diagnosis offers the only hope in malignant cases. The pharynx offers possibilities for the exercise of surgical skill in a minority of cases. Radiation by radium or x-rays is applicable to a larger group of cases and by modern methods has given encouraging results. The œsophagus is still the realm of experimental surgery and for all practical purposes is beyond the range of successful radiation.

Is the Practice of Contraception Injurious to Health?

By EARDLEY HOLLAND, M.D., F.R.C.P., F.R.C.S., F.C.O.G.

(Abstracted from the *Practitioner*, September 1933, Vol. CXXXI, p. 247)

THE EFFECT OF BIRTH CONTROL ON THE GENERAL HEALTH

For the moment I shall confine myself to the consideration of birth control as a general principle; particular contraceptive devices and methods will be considered later on. Does birth control injuriously affect the health of individuals or communities? How

are we to approach this problem? Precise statistical data are not available, nor, in a human population, are they ever likely to be. We have to rely on general impressions formed from the routine of common experience. The possibility that such a radical interference with the normal results of sex union may have disturbing effects cannot be denied. But I know of no reliable evidence in support of such a contention. It may be affirmed with confidence that in this and many other civilized countries 67-70 per cent of the married people have now adopted contraceptive devices of one kind or another, and any injurious effects would have been noted and named years ago. But search a modern textbook of medicine or the medical journals and you will find nothing.

Dr. C. V. Drysdale in a very able paper dealing with this aspect of the subject (see Report of the Sexual Reform Congress, London, 1929, p. 160) points out that if contraception, which may be regarded as perhaps the greatest of all modern changes in the habits of the people, has any serious physiological effect, it ought to be manifested by a diminution of vitality and longevity which would be revealed by an increased death-rate. On the contrary, as anyone may see who reads the Registrar-General's annual reports, there is no escape from the fact that as birth-rates have fallen, death-rates have fallen also and longevity has risen; and that these advantages have not been experienced to anything like the same extent in countries which have maintained high birth-rates. This certainly does not support the physiological injuriousness of contraception.

Perhaps more conclusive is the evidence given by the incidence of the death-rates at various ages. Dr. Drysdale presents a diagram which shows the ratio of the death-rates, at varying ages for men and women respectively, in the years 1920-21 to those of 1910-12. The figures show that from 16 to 25 years of age, at which latter age parenthood usually begins, the death-rate did not show much change, but from this age onwards there was a decided reduction of the mortality both for men and women amounting to 20 per cent for men and 21 per cent for women between the ages of 45 and 50 (about the end of the fertile age for women), after which the improvement lessened at greater ages. An improvement of 20 per cent in the mortality figure after an interval of ten years is remarkable and although preventive medicine and hygiene have made great progress in this time, it does, at all events, suggest that birth control has done no harm.

PSYCHOLOGICAL EFFECTS

The only psychological ill-effects I have noticed have been sometimes when people have had a failure with their contraceptive methods and have lost confidence in them, all sorts of disturbances in sex relations may then arise; and in people of a certain temperament a definite anxiety state may develop. The following case is an example:—

The wife of a medical man, after having three children, had a series of obstetrical disasters (two very premature labours and a complicated abortion followed by severe septic thrombo-phlebitis) in consequence of which further pregnancies were undesirable. Contraception was practised for a time successfully, but a pregnancy occurred which was terminated artificially and was followed by a severe form of septic infection. Confidence in contraceptives was lost and another pregnancy was dreaded. Sexual continence was for a time practised and then was succeeded by unsatisfactory sex-relations which revealed partial impotence on the part of the husband. Both partners were of a highly strung temperament and the husband became definitely neurasthenic; his work suffered, a long holiday did no good, and he was about, perforce to retire from practice. When his wife consulted me I at once proposed she should be sterilized. This having been effected, the whole situation underwent an immediate change, and harmony and successful work reigned once more.

DOES CONTRACEPTIVE PRACTICE DIMINISH THE NATURAL FERTILITY OF A WOMAN?

The belief still lingers that the prolonged use of contraceptives quite apart from the methods used, may have the unwished-for effect of diminishing or destroying the fertility of a woman, so that when a pregnancy is desired it may not occur or may occur only after a long delay. So far as I am aware no physiological theory which might explain this belief has ever been put forward; nor do I know of any experimental work, or of any controlled clinical observations which might support it. I believe it is often used as a bogey by persons prejudiced against contraceptive practice. It often exists as a vague fear on the part of the couple who, having used contraceptives, find that pregnancy does not quickly follow their disuse. The following example illustrates the sort of case in which this erroneous belief may arise:—

A young couple who for the first two years of marriage had used contraceptives consulted me because a wished-for pregnancy had not occurred although they had given up using contraceptives for six months. They were both distressed because they had been told, and believed, that the contraceptives had probably resulted in a prolonged or permanent state of infertility. I found the wife was the subject of mild hypothyroidism, and reassured her that her infertility was probably due to this and could probably be corrected by treatment. She was given thyroid gland and a diet low in calories but high in protein, and three months later reported herself pregnant.

ON THE UNWISDOM OF USING CONTRACEPTIVES BEFORE THE FERTILITY OF A UNION IS PROVEN

When a newly married couple consult me about contraception I advise them to let nature take her course to begin with and, unless there are good reasons to the contrary, to postpone the use of contraceptives until after the birth of the first child. The reason for this advice is that the fertility of any union may be much below the average, and that the practice of contraception may in consequence be not only unnecessary but positively disadvantageous, for it may have the unexpected and unfortunate effect of reducing the number of children below that which is desired. Without entering into discussion of that little understood subject of the variation of fertility (I exclude, of course, cases in which physiological or anatomical defect is demonstrable), I will merely state that cases are not uncommonly met with in which one or two conceptions seems to be nature's limit; and that cases occur in which the fertility of a union seems to endure only for a limited number of years, the fertile years being commonly the earlier years of marriage. Cases of 'one-child sterility' (better named 'one-child fertility') are not infrequent, in which the fullest investigation fails to reveal a cause for the limitation of fertility and the most careful treatment fails to correct it. Many cases of this sort are explicable only on the assumption that the fertility of the wife, or the combined fertility of wife and husband, is inherently limited. It is obvious that if, in such low fertility states, conception is prevented during the early years of marriage, absolute or relative childlessness may result. For these reasons it is wise for couples not to prevent conception until fertility has been proven. It is in these cases, also, that contraceptive practice may be unjustly blamed for destroying a woman's natural fertility.

ON INJURIOUS EFFECTS WHICH MAY ARISE FROM THE USE OF PARTICULAR CONTRACEPTIVE DEVICES

So far I have dealt only with the general principle of contraception and have not considered the particular devices which may be used to attain that end. The two ideals which should be aimed at are: (1) absolute reliability, and (2) absolute harmlessness. The former we know has not yet been attained; for the best statistics reveal that 3 per cent of intelligent people

who use contraception fail to achieve consistent protection whatever method be used.

As regards the attainment of harmlessness there can be no doubt that some devices are safe and incapable of causing any pathological condition of the female generative tract, and that some are highly dangerous. The various devices may be considered in two groups: (1) chemical; (2) mechanical.

The *chemical spermicide* most commonly used is quinine, and for many years quinine in the form of a soluble vaginal pessary, or of a jelly, has been popular. Quinine sometimes acts as an irritant to the vagina, and I have seen cases of mild vaginitis which I ascribed to this cause, chiefly because it quickly subsided when the use of quinine was discontinued. Compared with the wide use of this spermicide the proportion of cases in which it acts as an irritant must be very small indeed. One can only assume that some women have an idiosyncrasy in this respect. An important practical point is that the pessaries ought to be very carefully made in order to ensure that the quinine is equally distributed among them. This can be achieved if the work is done according to the prescription by a reliable dispenser. But most are manufactured in bulk and it has been found that sometimes the distribution of the quinine is most uneven, some pessaries containing hardly any and some a great excess.

A belief appears to be widely held that quinine if used over a long period of time may impair the inborn fertility of a woman. Experimental work has been recently undertaken in which quinine, chinosol and other spermicides were injected into the vaginas of dogs, rabbits and other animals over varying periods of time, and pathological changes in the endometrium sought for. The results were negative, no evidence of pathological effects being found. While not denying the possibility of temporary or permanent quinine sterilization—as it may be called—I have never come across any reliable clinical evidence of its existence. On the other hand, in common with many other medical persons, I have observed numerous patients who after using quinine for many years have found their fertility undiminished when a pregnancy was desired.

Mechanical devices.—It is difficult to see what possible harm can be done by the vaginal occlusive pessary which is introduced and removed by the woman herself, according to requirements. On the other hand, the rubber cap which is fitted over the cervix and left there for a period of time should not be recommended, for it prevents drainage from the cervix and may lead to chronic cervicitis, when added dangers may arise. The devices calling for most serious criticism are the cervical stem and the intra-uterine ring (Gräfenberg's ring).

Cervical stems, fortunately, are nowadays scarcely ever used in this or in any other country. They consist of hollow pins, of gold, silver or other uncorrodible metal, with a button-like lower end to fit over the external os, and some sort of intra-uterine self-retaining device, usually a pair of divergent arms which are held together during the process of introduction and then spring apart. The apparatus is presumably introduced by a doctor and is left in position for some months. It is difficult to believe that such a device can be introduced by anyone but a dangerous crank. It establishes communication between the bacterial flora of the vagina and the uterine cavity, and dams drainage. Pregnancy may take place in spite of it and abortion follows. Numerous cases of severe infection have accompanied its use, with pyosalpinx and even fatal peritonitis. The device is mentioned here only to be utterly condemned.

Gräfenberg's ring is a device which is entirely intra-uterine and not vagino-uterine, as is the cervical stem. The ring is made of a closely coiled spiral of fine silver wire and its pliability allows it to be passed through the cervical canal into the uterine cavity where it regains its circular form. As it is separated from the vagina by the whole length of the cervical canal, the

ring does not favour the passage of bacteria from the vagina into the uterine cavity, as does the cervical stem device. It is allowed to remain in the uterus for a year and is then removed and may be replaced by a fresh one.

Gräfenberg's ring has gained very few adherents among gynaecologists in this country, though it appears to be used extensively in certain continental countries. The objections commonly urged against it are: (1) It is not a reliable contraceptive; (2) it is liable to be expelled from the uterus without the woman being aware of the loss; (3) it may cause uterine sepsis. I cannot speak of its use from personal experience, as I have always had a prejudice against it, and have been persuaded to use it on only two patients. One, who had suffered from recurrent toxæmia of pregnancy, returned to me, six months after the ring had been inserted, in the second month of pregnancy. A radiogram showed that the ring was no longer in the uterus, but the patient had not noticed its exit.

Gräfenberg's ring is much used, in suitable cases, by Dr. Norman Haire, who is justly regarded as one of the most experienced contraceptive experts. He points out, in the proceedings of the Seventh International Birth Control Conference of 1930, that due precautions must accompany its use. It is, for example, necessary that the patient should be examined carefully beforehand by a competent gynaecologist, and that she should report at once to him any symptoms arising while the ring is in position. If the patient has an infected cervix, or any other form of genital infection, the ring is dangerous and on no account should be inserted until the infection is cured. If the patient acquires gonorrhœa or any other infection while the ring is in place it can cause an aggravation and spread of the infection and should be at once removed. Haire admits that in exactly 13 per cent of his cases the ring was expelled; but when subsequently a ring of a different size or elasticity was inserted it stayed in. He also points out that if a patient becomes pregnant in spite of the ring an abortion does not always follow; he has confined two patients of a baby *plus* a ring, and both the pregnancies and labours were normal and the children healthy and undamaged. With due precautions he considers the ring to be a harmless method of contraception.

On the other hand, at this same Conference, those who were against Gräfenberg's ring appeared greatly to outnumber those who were for it. Dr. Leunbach, of Copenhagen, on the basis of 176 cases was decidedly of the opinion that the ring fails in the two essentials of harmlessness and reliability. In 21 cases he had to remove the ring because of uterine bleeding between the menstrual periods, or menorrhagia. Four patients in whom the ring came out unnoticed became pregnant. Pregnancy not seldom occurred with the ring in place, and if abortion ensued he found that the presence of the ring increased the risk of complications. In three cases there occurred acute pelvic inflammation, salpingitis or parametritis. Dr. Frey, of Zurich, a very able gynaecologist whom I have had the pleasure of seeing at work in the University Women's Hospital in that city, was very strong in his condemnation of all intra-uterine devices. He did not know, he said, who were most to be pitied, those who recommended and inserted them or those women who were fitted with them. He told the Conference that the Medical Society of the Canton of Zurich had taken a definite stand and had suggested that they should no longer be used, and that the Swiss Government had forbidden their sale. It is true he was not able to report any fatal cases from the use of the Gräfenberg ring, but only two 'complicated cases'. He reported three fatal cases from the use of a cervical stem. But he considered that the difference between the ring and the stem was only one of degree.

CONCLUSION

I would sum up my views as follows: (1) Contraception, as a principle, on the evidence available,

cannot be said to exert any injurious physiological or psychological effects. (2) Vaginal occlusive pessaries if used according to the ordinary common sense rules of vaginal cleanliness can do no harm. (3) There is no reliable evidence that quinine preparations used in the vagina as a spermicide can do any harm, or can diminish or destroy a woman's inborn fertility. (4) Gräfenberg's ring should be recommended and used only by competent gynecologists who are experienced in the method and who are thoroughly aware of the precautions which should accompany its use. (5) It should be made a criminal offence to sell or use for contraceptive purposes a cervical stem.

Leprosy in the Philippines

By M. E. HIGGINS

(From the *United States Nav. Med. Bull.*, Vol. XXXI, October 1933, p. 363)

LEPROSY is one of the outstanding health problems of the Philippines. The Culion colony with its 5,700 patients is probably the largest leprosarium in the world. There are approximately 2,000 lepers segregated at other places, so that the total number under observation is about 8,000. Excellent facilities are afforded for study and research and Philippine workers have made and are making valuable contributions to our knowledge of the disease. A more recent bibliography compiled by the Director of the Philippine Health Service cites 177 references in the literature from Philippine sources.

The writer has recently visited the leprosaria at Culion, Iloilo, Cebu, and Zamboanga. At all of these stations every opportunity was afforded him to observe the medical and administrative procedures employed in the management of the disease.

Culion is an island with an area of nearly 200 square miles lying 250 miles south of Manila. The Culion Leper Colony was established in 1906 as the principal centre for the segregation and treatment of leprosy. It is also the chief centre for bacteriological and pathological research and for the manufacture of antileprosy drugs.

The colony has a 500-bed hospital, dormitories for 2,000 patients, clinic buildings, and laboratories. These buildings are of concrete construction. In other respects the colony resembles the ordinary Philippine town, most of the houses being bamboo and nipa construction of the type commonly seen throughout the islands. As far as practicable the patients are encouraged to carry on their usual vocations; some manage retail shops; others are engaged in fishing; a number cultivate small farms on the outskirts of the town and sell their products in the colony.

There are about 1,000 nonlepers on the island—physicians, nurses and administrative assistants who live in a special reservation separated from the main colony.

A portion of the island has been set aside for the development of an agricultural community to be operated by paroled lepers who can no longer be cared for in the colony proper, but who do not, for various reasons, wish to return to their former homes. This 'negative varrio' is 16 kilometers from the main colony and is reached by an excellent road constructed almost entirely by the patients themselves.

The Eversley Childs Treatment Station near Cebu is the second most important station in the Philippines. It was designed to accommodate 500 patients and built under the auspices of the Leonard Wood Memorial. It consists of a hospital, dormitories, clubhouse, administrative buildings, and a chapel—all of concrete construction. The ample grounds have been attractively laid out and planted with a variety of palms and flowers so that the general effect is extremely pleasing.

The Western Visayas Treatment Station is located on the island of Panay near Iloilo. It accommodates

275 patients. All of the buildings at this station are of temporary or light construction.

The central station for the island of Mindanao is at Zamboanga. A new 50-bed frame hospital has just been completed; it replaces a number of small structures of temporary construction.

In addition to the above stations the Bihol Treatment Station in southern Luzon and the San Lazaro Hospital at Manila accommodate about 800 cases. There are also a number of substations throughout the Philippines where cases can be held temporarily pending transfer to one of the central stations. In the larger cities skin clinics have been established which are proving to be a valuable factor in the detection of incipient cases.

The Leonard Wood Memorial is a \$2,000,000 foundation established in memory of General Wood who was much interested in the control of leprosy. It works in close co-operation with the Government Health Service and is especially interested in research work bearing on the ætiology, pathology, and bacteriology of leprosy. Its chief activities are at Culion and Cebu. At the former place a thoroughly equipped laboratory and experimental wards are nearing completion. At the Eversley Childs Station at Cebu which was built by the foundation at a cost of \$200,000, it is proposed to devote particular attention to the question of ætiology.

Dr. H. W. Wade, who was for many years the director of the pathological section at Culion, is the field director of the memorial with headquarters at Culion.

Observations in the Philippines bear out the generally accepted belief that leprosy is a familial disease and that infection occurs almost exclusively during infancy and early childhood. Adult infection seems to be extremely rare. During the 25 years that Culion has been in operation there has not been a single case of the disease developing among the physicians, nurses, and attendants. One Sister of Charity who has been in the colony since its beginning and in the most direct contact with active cases has remained free from infection.

It is estimated that 95 per cent of all cases occur among the poorer classes. Bad hygienic surroundings and defective diet undoubtedly play a prominent rôle in determining susceptibility to the disease.

The ethyl esters of the oil of the *Hydnocarpus wightiana* are now generally used throughout the Philippines in the treatment of leprosy. The crude oil is imported from India and refined in the chemical laboratories of the Culion colony. One half of 1 per cent metallic iodine is added to the esters in order to lessen irritation. The drug is injected either intradermally or intramuscularly. Usually a combination of these methods is employed. The total dose is 5 cubic centimeters. When given intradermally not more than 0.1 cubic centimeter is injected at any one point. Injections are made two or three times weekly. The site of the intradermal injections is marked by a characteristic bluish discoloration which may last for several months. The general belief in the Philippines is that this treatment does not cure the disease. 'Once a leper always a leper' is an opinion frequently expressed by many experienced workers. There is no doubt however that acid-fast organisms disappear from nasal and dermal lesions and that the progress of tubercular lesions is arrested. These are the 'negative' or 'arrested' cases that are paroled. It has been found that a considerable number of these paroled cases again become active.

Apparently the question of diet as a therapeutic measure has not been given any special consideration, chief reliance having been placed upon segregation and the administration of chaulmoogra oil. It is generally recognized that the diet of the poorer classes is not well balanced, being deficient especially in proteins and fats. Vitamin deficiency also occurs. Beriberi is not infrequently a concomitant disorder. Since vitamin B is often lacking it is not unreasonable to suppose that other important factors are inadequate. Certain observers believe that a scientifically-controlled diet

and hygienic management along the lines now employed in the treatment of tuberculosis may have a profound effect upon the progress of early leprosy. Apart from the similarity of the causative agents the parallelism existing between tuberculosis and leprosy is striking.

Segregation and chaulmoogra oil have apparently failed to make any marked reduction in the number of cases of leprosy occurring annually in the Philippines. Under present conditions the eradication of the disease will have to wait upon such slow factors as rising cultural and economic levels. Additional measures that have been recommended include the removal of the children of leprosy parents at birth, the sterilization of the male lepers, and birth control. The application of all these procedures is attended by manifest difficulties. The education of the masses regarding early diagnosis and treatment has yielded valuable results. At all of the stations more and more people are voluntarily applying for examination and treatment. One hopeful feature in the control of the malady is that it is no longer regarded with the exaggerated horror which has so long characterized the public conception of the disease.

The expense incident to maintaining 8,000 lepers in segregation places a great strain on the budget of the Philippine Health Service. It is estimated the Government has expended \$11,000,000 on the control of leprosy since the establishment of the Culion colony in 1906.

At the present time nearly one-third of the health appropriations is devoted to leprosy. Many physicians feel that this amount is inordinate and that some of the funds now devoted to leprosy should be expended in the fight against tuberculosis, a disease in which the mortality and morbidity are vastly greater. The number of lepers in segregation is constantly increasing and practically all the stations are at their capacity level. Unless some means can be found to lessen this growing financial burden, the situation will soon become a serious problem.

SUMMARY

- (1) There are at present about 8,000 lepers in segregation in the Philippines.
- (2) The iodized esters of the oil of the *Hydnocarpus wightiana* are used in the treatment of the disease.
- (3) The consensus of opinion is that permanent cure is not obtained.
- (4) In early cases marked improvement occurs in tubercular lesions; acid-fast organisms disappear from nasal and dermal lesions.
- (5) Adult infection is extremely rare, the belief being that infection takes place during infancy and childhood.
- (6) The control of leprosy absorbs one-third of the funds available for health work in the Philippines.

Reviews

HEREDITY AND THE SOCIAL PROBLEM GROUP.—

By E. J. Liddbetter. Volume I. Edward Arnold and Co., London. 1933. Pp. 160. Illustrated

The study of poverty and pauperism has for long been a favourite one with statesmen, public-health workers, and social reformers. Indeed it is hardly an exaggeration to say that we owe the real beginnings of public health in England to the rapid growth of pauperism in the early years of the industrial revolution. Sir Edwin Chadwick and John Wesley—one the Secretary of the Poor Law Board of England, the other a clergyman discontented with the *laissez-faire* attitude of the educated and governing classes of England towards the destitution of the lower classes in the early years of the 19th century, set aflame the scientific and humanitarian consideration of poverty, vice, misery, and disease. By gradual and sound legislation on the one hand and the development of a spirit of responsibility, toleration, and consideration on the other, the beginnings of public health in England were laid in 1840.

The study of heredity is an old one and the fact that like tends to beget like needed little scientific observation or proof. Mendelism, however, and the minuter study of cellular genetics have shed new light on the actual mechanism of plant and animal inheritance. Then arose the question, could these facts be used in the improvement of the human race, to favour the development of desirable characteristics, and to discourage the production and perpetuation of undesirable traits? Animal herds had for long been improved by selective breeding.

Eugenics, as applied to the human race, is striving towards becoming a science and a moving force. Sir Francis Galton, who founded the Eugenics Society, cited his own family as one which had produced many brilliant and distinguished men and women by a judicious blend of three intellectual families, the Wedgewoods, the Darwins, and the Galtons. Others like Dean Inge have given similar instances. On the other hand many pedigrees of degenerate families (the Jukes and Kallikaks, for example) have been studied with the object of showing that laziness, criminality, and

viciousness appear in generation after generation with such regularity and insistence as to suggest hereditary significance. Whether heredity or environment determines human characteristics is still a favourite battle ground. Both undoubtedly are of importance, sometimes one and sometimes the other playing the major part. Whether mental qualities are of the same *genre* and are transmitted by recessive and dominant genes in the same way as eye-colour, hæmophilia, left-handedness, etc., is still a very moot question. Galton's own studies of 'regression' suggested that nature works towards an average both from above and below. On this basis genius and high intellect on the one hand will always be rare, but so on the other hand will gross viciousness and desperate criminality; and just as the progeny of very clever people are more likely than not to be more ordinary than their parents, so there may be no necessity to postulate a criminal progeny to vicious or criminal parents.

Mr. Liddbetter has been connected with the administration of the Poor Law in England for many years and the present volume is a close study and collection of 26 pedigrees of the members of families who exhibited various disabilities, bodily, mental and moral, which resulted in pauperism, insanity, vice and criminality. The pedigrees consisting of histories and characteristics are given in great detail in diagrammatic and narrative form. The exact value of the collection will be argued. Mr. Liddbetter draws no conclusion as far as one can see. Major Leonard Darwin in an interesting preface suggests that the materials collected by Mr. Liddbetter will be of enormous value to future students of social problems. He concludes 'as long as this wretched stream of social inadequacy continues to flow in the appalling way indicated by these pedigrees, and whatever be the part played by nature and nurture, the nation would gain greatly if all those definitely inferior to the bulk of their fellow citizens were to have no children or but small families'. Most thoughtful people might agree to this at first sight but on more careful thought will conclude that the statement is too relative to mean

much. Several states have tackled the problem, but as yet no solution is evident. Those interested in the future of eugenics will like to have the volume for reference.

A. D. S.

A SIXTH VENEREAL DISEASE.—By H. S. Stannus, M.D., Ph.D. (Lond.), F.R.C.P. (Lond.), M.R.C.S. (Eng.), D.T.M. & H. (Cantab.). 1933. Baillière, Tindall and Cox, London. Pp. xli plus 270, 9 plates. Price, 12s. 6d.

UNDER the title 'a sixth venereal disease' are included two main venereal diseases, climatic bubo, a disease of the tropics, and lymphogranuloma inguinale, a condition recognized in Europe and America, together with a host of other clinical conditions, such as esthiomene, chronic ulcer, and elephantiasis of the genito-anal region, inflammatory stricture of the rectum, and several allied conditions. The diversity of opinion that has been held in the past, in regard to the aetiology of these several affections, led to the coining of several names to describe different clinical entities in different parts of the world. It was not till it was established that these several conditions yield the same specific filtrable ultra-microscopic virus, and that the histopathological picture, whatever the lesion, whether in man or experimental animals, is practically the same and that variations are variations not in kind but in degree according to the activity of the virus and the stage in the process, that the identity of these several conditions was obtained. The author, who as a sectional editor of the *Tropical Diseases Bulletin* was particularly fitted by his extensive knowledge of the subject, has given, in this monograph, a detailed and critical review of the whole subject in all its aspects and with a very complete bibliography which contains 933 references. In using the designation 'sixth venereal disease', no suggestion is made that such a term should come into common usage, but it serves the very useful purpose, however, of bringing together under one heading several conditions which were at one time held to be several different entities. The author suggests the term 'poradenitis' as a general term which can be qualified to describe different clinical conditions. The other five venereal diseases are syphilis, gonorrhœa, chancre, genital infection by Vincent's organism (the 'fourth venereal disease' of some American writers) and granuloma venereum (ulcerating granuloma of the pudenda).

This is an excellent book; it contains reviews of all published cases of this very interesting disease and a general summary of the history, the clinical manifestation and a critical digest of all the research work that has been done on this condition. It is a book that will appeal to those engaged on research work on filtrable viruses, to the venereologist and to the practitioner of medicine who will find much in it that will help him in the proper diagnosis of many venereal conditions that have been labelled so far by different names.

C. L. P.

HISTOLOGY.—By S. Ramon-Cajal, M.D., F.R.S., LL.D. Revised by J. F. Tello-Munoz, M.D. Authorized translation from the tenth Spanish Edition by M. Fernan-Nunez, M.D. 1933. Baillière, Tindall and Cox, London. Pp. xiv plus 738, with 535 figures. Price, 40s.

THIS book has been translated by a Spanish medical man practising in America. In his preface the translator explains that it is a student's textbook of elementary histology, and he goes on to describe briefly the extensive histological knowledge that the Spanish medical student has to absorb. It is certainly not elementary according to the usual English standards.

The book is said to be a literal translation as far as possible, which makes the nomenclature and phraseology unusual from the English point of view, nevertheless it is remarkably clear and there

is no difficulty in following the descriptions. This is surprising when it is noted that strictly American spelling has been added to the literal Spanish translation.

The first seven chapters are devoted to considerations of cells in general, dealing with structure, physiology, chemistry, division and evolution. These are extremely interesting and might be read with profit by anyone interested as they give an unusual perspective of the subject. This latter remark can be taken to apply to the whole book for the descriptions throughout give quite a new conception to the histology of the various organs, from that usually gained from English or American books, but of course the underlying facts are unaltered. Perusal of this book therefore has the effect of considerably broadening one's vision of histology.

Another unusual feature is the large number of original illustrations. These are beautifully executed, but so much detail is displayed that one feels that most of the figures are not actual drawings, but probably composite semi-diagrammatic sketches, this impression is strengthened by the fact that nowhere is the magnification given. Nevertheless they are of very great instructive value.

It is not a book that can be recommended to students who are being instructed on the usual lines of British medical schools, and whose primary object is to pass the examiners, but it might be read with profit as an adjunct to their regular teaching.

P. A. M.

HISTOPATHOLOGY OF THE PERIPHERAL AND CENTRAL NERVOUS SYSTEM.—By G. B. Hassin, M.D., 1933. Baillière, Tindall and Cox, London. Pp. xiv plus 491, figures 227. Price, 30s.

THE inadequacy of the space usually allotted to the study of neuropathology in ordinary clinical manuals on neuro-psychiatry and the fact that neuropathology is essential to the proper understanding of clinical phenomena led the author to prepare this volume. Diseases of the peripheral nerves, spinal cord and brain are described individually from a histopathologic angle only, and in order to keep the book as concise as possible, reference to the clinical aspects of the subject have been made very brief.

The book is divided into four parts dealing with diseases of the peripheral nerves, the spinal cord, the brain and a last part containing a very useful summary of staining methods which have been found useful in histopathological work of the central nervous system. At the end of each chapter is given a very useful bibliography. Altogether this book is well conceived and well written, has excellent illustrations, and should prove of value to advanced students, particularly those engaged in the study of neuro-psychiatry.

C. L. P.

A POCKET GUIDE TO MEDICAL LIFE ASSURANCE.—By J. J. Cursetji, M.D., L.R.C.P., L.R.C.S., L.M. & S., F.C.P.S. (Bom.), J.P. Third Edition. 1932. Printed at the Union Press, Bombay. Pp. 274. Price, Rs. 6-8, cloth binding and Rs. 5-8, bound in thick cardboard cover

THIS small book is written by a medical man who has had a long experience of life assurance in India, and in consequence it is full of valuable advice, especially to a practitioner who is called upon to make examinations at rare intervals, but it might also be read with profit by experienced medical examiners and should certainly be kept where it may be referred to readily.

Naturally it will be of most use in India and here it will be found of special assistance because it gives valuable comparative information about the numerous different races and religious sects in the country, whose different customs and modes of life have a powerful influence on their health. At the same time this book will be of use in any part of the English-

speaking world as it is full of well chosen quotations and examples drawn from the experiences of the principal British and American officers.

BLOOD PRESSURE IN LIFE ASSURANCE PRACTICE.

—By J. J. Cursetji, M.D., L.R.C.S., L.R.C.P., L.M. & S., F.C.P.S. (Bom.), J.P. 1931. Printed at the Union Press, Bombay. Pp. 16

THIS pamphlet of sixteen pages begins with a clear and well illustrated description of how the blood pressures (systolic and diastolic) should be taken. It is so clear that any medical man might purchase a sphygmomanometer and teach himself how to perform the operation, without any personal instruction.

This is followed by a general outline of the significance of blood pressure readings in health and disease, and at the end there are two tables giving comparative figures for Americans and Canadians and a third table compiled from observations made at the Oriental Life Assurance Company, Bombay. It is an eminently practical little publication.

AIDS TO SANITARY SCIENCE AND LAW.—By C. F.

White, M.B., Ch.B., D.P.H., D.T.M. Second Edition. 1934. Baillière, Tindall and Cox, London. Pp. vii plus 321. Price, 4s. 6d.

SANITARY science and sanitary law are undoubtedly extremely interesting subjects, but attempts to compress them into a small compass invariably seem to produce uninteresting and rather repellent skeletons that miss all the attractiveness of the living agencies. The present book is hardly an exception to the rule. A great deal of matter has been collected in various chapters, but it is all unconnected and the style resembles a collection of notes and jottings. This is almost unavoidable in a book of this nature.

To judge correctness of information, one turns naturally to the sections on tropical diseases. The information is meagre and often at fault. It is rather surprising that cholera is not mentioned here. It is only mentioned casually under the Port Sanitary Regulations of 1933. It is surely one of the most important 'tropical' diseases from the temperate climate point of view.

Xenopsylla astia is not mentioned under plague. The causal organism of yellow fever is stated to be *Leptospira icteroides*. This view is not held by any one now. Ticks, under relapsing fever, are spelled 'tics'. Under malaria, quinine is stated to be a prophylactic, if given at the right time—no mention is made of recent observations of James, Swellengrebel and others.

Sanitary law is summarized, but no discussion of administration is given.

The book is not likely to be of any great assistance to public-health students in India or other tropical countries.

ACTINOTHERAPY TECHNIQUE: AN OUTLINE OF INDICATIONS AND METHODS FOR THE USE OF MODERN LIGHT THERAPY.

With a Foreword by Sir Henry Gauvain, M.D., M.Ch., F.R.C.S. 1933. The Solflux Publishing Company. Pp. 184. Price, 6s., postage 4d.

MANY books have been written on this subject but the book under review is in some ways exceptional. There are a few introductory chapters on such subjects as physical data, physiological effects of different rays, dosage, and heat rays; the rest of the book is then divided into chapters on the treatment in different morbid conditions.

Every statement has the full authority of an article in some well-known medical journal. The method of administration of the rays, usually ultra-violet, sometimes infra-red, is described, the suitable dose suggested, the instrument to be used recommended, and any special dangers that are to be avoided are pointed out.

It should prove a useful book to the general practitioner who wishes to use actinotherapeutic methods.

It is, however, an uncritical book and unsuitable for the younger students of medicine. If the decision to use actinotherapy is arrived at independently, the book will be a useful guide, and in this capacity we can confidently recommend it.

AN OUTLINE OF PRACTICAL OBSTETRICS FOR NURSES.—By R. S. S. Statham, O.B.E., M.D.,

Ch.M., F.C.O.G. 1933. John Wright and Sons Ltd., Bristol. Pp. 139. Price, 2s. 6d.

THE author's avowed intention was to write a small book, 'solely for the purpose of revision', for the Central Midwives Board Examination. Its convenient size is designed to ensure that it will be carried about with the nurse and help to pass profitably some of the long hours of waiting when she is conducting domiciliary midwifery cases. For nurses who appreciate and can learn from 'cram' books it will prove useful, though the lack of diagrams for reference when reading the first two chapters on the anatomy of the female pelvis and genital organs, and on the ovum and foetus will be rather a serious handicap to any one not absolutely familiar with the pictures, models and specimens of the class room.

Facts are cut down to a minimum and discussion of procedure is incompatible with the size of the book. There is danger in this and the nurse may rest content with the statement that it is advisable that one antenatal examination by the doctor should take place and that at the 32nd week of pregnancy, rather a late date at which to begin preventive measures. The nurse is more capable of detecting abnormalities of proportion or presentation than of assessing the woman's fitness for pregnancy, and the later examination rather than the earlier can better be left to her when only one is to be undertaken.

The nurse has responsible duties with regard to the establishment and management of breast feeding and while this is not stressed in the present Central Midwives Board syllabus, perhaps something might be added about it at the expense of manipulations and the administration of anaesthetics, such as nitrous oxide, which are only within the province of the doctor.

J. M. O.

Abstracts from Reports

ABSTRACTED FROM THE ROCKEFELLER FOUNDATION, ANNUAL REPORT FOR THE YEAR 1932

Part II

In our last number we gave an abstract of the portion of this report dealing with yellow fever research, and although this is a comparatively new addition to the numerous activities of the Rockefeller Foundation all its other branches of inquiry are still being conducted as actively as ever and a brief résumé of them is given below.

MALARIA

The malaria problem

The general principles of malaria propagation have been known for a third of a century; yet malaria prophylaxis is still a perplexing problem, and malaria remains the king of tropical diseases.

Malaria control through eradication of the mosquito vector is comparatively simple if expense need not be considered. But to control this disease when expenditures must be kept within the average public health budget is a far more difficult task. The problem is to bring control work within the economic means of the community.

To determine the logical procedure necessary in combating malaria in any particular area a careful study must be made. An important part of all malaria control work is malariometry. By noting parasite, spleen, sporozoite, and mosquito indexes during and after the administration of prophylactic measures, it is possible to make a fair estimate of the return that is being obtained for antimalarial expenditures.

If patients could be segregated it would be possible to apply the slogan 'Do not infect the mosquito and the mosquito won't infect you'. Unfortunately such segregation is usually impossible.

Generally speaking, the drugs that are specific for malaria are expensive and are not easily administered on a large scale. Quinine is extensively used, but it has marked limitations. It is effective against symptoms; it has saved innumerable lives; but it is not a preventive of the disease. In areas where attempts have been made to control malaria by means of quinine, better food, better housing, and better hospitals, the effect on the prevalence of the disease has been practically nil. On the other hand, wherever efforts have been directed against the mosquito vector, malaria has decreased and its spread has been controlled.

Some results can be obtained by killing adult mosquitoes through such methods as swatting, catching, spraying, fumigating, trapping, the use of poison baits, and the encouragement of natural enemies. However, not a great deal can be expected from such methods, because they require the systematic and continuous co-operation of the individuals of a community, and this, except under army conditions, is rarely possible of achievement.

Other methods aim at preventing the mosquito from biting. These include screening, special clothing, bed nets, chemical or mechanical repellents, removal of houses from malarious districts, provision of animal barriers, and best of all, the killing of mosquito larvæ.

The destruction of larvæ can be accomplished in a number of ways. One of them consists in oiling the surface water in which mosquitoes breed. But such oiling can serve only as a temporary measure. Continued for many years, it is frequently found to be more expensive than permanent control measures, such as draining or filling. Larvæ can also be killed by dusting Paris green on the water in which they are found. This measure is effective even if the Paris green is extensively diluted with road dust or some similar substance. There is no evidence of the danger of Paris green, when used in this way, to life other than that of mosquito larvæ. It has never poisoned human beings, live-stock, or even fish in the waters in which it has been used. It has no ill effects on rice or other crops. On the other hand, it does not kill mosquito eggs or pupæ. It is also not so easily visible as oil, and is therefore more difficult to control by means of inspection.

Encouragement of the multiplication of the natural enemies of the mosquito, especially small larva-eating fish, is a simple and effective way of controlling mosquito production. The top minnow is particularly useful for this purpose, but in few places in the world have fish alone been able to control malaria. They are of use chiefly as an adjunct.

The larvæ of the yellow fever mosquito can be trapped, because the mosquito which carries this disease breeds chiefly in artificial water containers found around houses; but trapping of the larvæ of the malaria-carrying mosquito would not be feasible, since this mosquito will breed wherever suitable water or moisture can be found.

The more radical and most successful methods of combating the malaria mosquito consist in destroying its breeding places by means of drainage, clearing, cleaning, channelling, emptying, filling, flushing, and drying, impounding, salting, or altering the composition of the water; and above all, by the orderly progress of agricultural cultivation, which tends to do away with

swamps and breeding areas. The economic improvement represented by progressive cultivation supplemented by the passage of the necessary sanitary laws, which usually follows enlightened public interest, is in the long run the most effective means of abolishing malaria.

In no single region is it necessary or feasible to apply all the antimalaria measures known. Each region presents a special problem. For this reason, as the late Sir Ronald Ross pointed out, success depends 'on the intelligence, enthusiasm, and energy of those who are responsible for sanitary affairs'.

The above passage from the report indicates the numerous aspects of the malaria problem which are receiving attention and the next twenty-five pages are devoted to accounts of these inquiries in various parts of the world. These accounts are of considerable interest but they do not readily admit of abstraction so they have had to be omitted on account of lack of space.

Hookworm disease

The following brief passage taken from the report gives an outline of the history of hookworm control from the beginning, and, as this is the basis on which the world-wide activities of the Rockefeller Foundation have been built up, it is given in full.

Early campaigns.—The work of the Rockefeller Foundation in public health had its origin in the Rockefeller Sanitary Commission for the Eradication of Hookworm Disease, which began activities on 26th October, 1909. At the start certain administrative principles were adopted which have proved to be well founded and which have been followed ever since. Work was undertaken only with state or government co-operation. Activities were carried out as far as possible through existing agencies. Each country has its own system of organized medicine, its own public press, public schools, and public health service. These four established institutions, rooted in the life and traditions of the people, are fundamental to all health education. To enlist these agencies in an undertaking is to assure permanency of work from the beginning. An outside agency can be helpful only in so far as it aids the state in organizing and bringing into activity its own forces.

The first field work of the Sanitary Commission was in the control of hookworm disease. By the time the Rockefeller Foundation was established, 14th May, 1913, the Commission had treated or caused to be treated more than 500,000 hookworm sufferers in the United States. The Foundation took over the work of the Commission and prepared to extend the hookworm campaign to other countries.

The plan adopted in 1913 was to make a survey of the geographic distribution of hookworm disease and the approximate degree of infection obtaining in infested areas; then to undertake microscopical examination of faeces and treat persons who were found to be infected; and finally to set in operation and make effective such sanitary measures as would put a stop to soil pollution. Hookworm work was rapidly extended throughout the Southern United States and then to the British colonies and to a large part of tropical Latin America. The work was most successful in bringing about cures and improving sanitation, and it also served as a foundation on which a general health service could be built up.

As hookworm control measures were extended, the need for more investigative work was felt; and this was started when Dr. S. T. Darling, Dr. M. A. Barber, and Dr. H. P. Hacker were commissioned, in 1915, to make studies in the Orient on hookworm disease. The programme of research work combined with field work thus initiated has never been abandoned. Research work, which casts light on the nature of the problem and leads to the improvement of methods, has been emphasized more and more. As a result, better work at diminishing cost can now be carried out. The opportunity for productive studies is not exhausted.

Research on the question of immunity against helminths and the effect of diet on susceptibility to in-

fection are being carried out on a large scale in the laboratory. Dogs and the dog hookworm are being used for this purpose. Another important branch of hookworm research that is receiving continued attention is the search for better drugs, and the current report records the experiences with the use of hexylresorcinol.

The common cold, undulant fever, yaws, and tuberculosis are all being investigated in one or more parts of the world and numerous miscellaneous studies of less general importance are mentioned.

Public health institutions are still being assisted in very many countries and we give below that part of the report that deals with the Foundation's work in India and Ceylon.

Owing to the economic depression, the disturbance of public order, and reduction of personnel and appropriations, public health work throughout the East has encountered a difficult situation. Notwithstanding discouraging circumstances much progress has been made. During 1932 the Rockefeller Foundation contributed to budgets for public health work under supervision of Foundation representatives in the following countries: Ceylon, India, China, Egypt, Netherlands East Indies, the Philippine Islands, and the South Pacific Islands.

During the year there was published an account of the health units which the Government of Ceylon is establishing in rural and semirural areas of the island. The organization of an official unit is described, and an account is given of its work, methods of operation, and manner of budgeting. Experience indicates that the needs of a rural area are well met by such units, and their establishment has aroused considerable interest among health workers and the general public.

In the State of Mysore in India, a Foundation representative continues to serve as a consultant to the government on health matters. A local health unit started in 1930 with assistance from the Foundation is operating under government auspices and with government funds. In 1932 the Bureau of Sanitary Engineering, which is under the direction of a Foundation representative, carried on experiments in composting night soil and refuse (*vide Indian Medical Gazette*, Feb. 1934).

Five visits were made to the State of Travancore by the Foundation representative stationed in Ceylon. At a town situated 12 miles from the capital city of Trivandrum, a health unit organized in 1931 with Foundation aid is making favourable progress under the supervision of a former Foundation fellow. A comprehensive public health programme is carried out by trained personnel. Special efforts are directed against malaria and hookworm disease. A Division of Public Education was started in 1932, towards the budget of which the Foundation make a contribution. The officer in charge is provided with cinema apparatus, a motor truck, and other material for health propaganda.

In order to test the possibility of successfully maintaining a local health unit under Indian conditions, the Foundation is co-operating with the health services of the United Provinces in the establishment of a health centre in Partabgarh, an area of 60 square miles with a population of 50,000. The health centre is organized along the lines of those in Ceylon. The work is directed by a former Foundation fellow.

We regret that it is quite impossible adequately to describe the work of this great organization in a brief abstract and we can do no more than mention the assistance that has been given to various countries in the form of building colleges for the training of medical students and nurses, the equipment of laboratories, and the granting of fellowships to enable promising students to visit other countries for the purpose of study.

The above abstract has only dealt with the work of the International Health Division of the Foundation, but in addition there are large sections devoted to Medical, Social, and National Sciences and the Humanities.

ABSTRACTED FROM THE ANNUAL RETURNS OF THE HOSPITALS AND DISPENSARIES IN BIHAR AND ORISSA FOR THE YEAR 1932

THERE was an increase of three in the number of dispensaries, eight being opened and five closed during the year.

The general health of the province appears to have been considerably better than in 1931, for the deaths from all causes except that of smallpox were distinctly lower, and in spite of the fact that this disease accounted for an increase of over 8,000 deaths the death-rate from all causes was 20.6 as against 26.6 per mille in 1931.

Four more leprosy clinics were in operation during 1932 and 2,355 more patients were treated than in 1931, indicating that more persons are being induced to attend for treatment.

It is also noted that there was a slight increase in the number attending for venereal infections in their early stages.

ABSTRACTED FROM THE ANNUAL REPORT OF THE EAST GODAVARI DISTRICT MEDICAL ASSOCIATION FOR THE YEAR 1933

WE have received a copy of the annual report of this association for the year 1933, and an account of the second anniversary general meeting.

This is a young association but it exhibits signs of robust health for already it has 157 members, fifty of whom joined this year. On account of the extent of the district the monthly meetings are held in rotation in different centres. This is a good way of giving all the members an opportunity of attending at least some of the meetings during the year.

The association combines clinical and scientific meetings with gatherings of a social nature and from the brief account of those given in the annual report they appear to have been highly successful from both points of view. The average attendance at these monthly meetings is 52 which appears to be a highly satisfactory figure to us but the secretary is not at all satisfied with this.

The annual meeting was held at Cocanada and it took the form of a business meeting, followed by a tea party. There was then a meeting, when several interesting papers were read, and a very successful function was concluded by a dinner. One hundred and one members, twelve medical men who were non-members and many lay visitors attended. Major T. S. Shastri, I.M.S., has again been elected president, and we gather from the remarks on this officer in the report that it is he who is mainly responsible for the success of this young association.

We extend our hearty congratulations to this organization and wish it continued success, for the formation of such societies, which devote the whole time at their disposal to meetings of a solely scientific and social character and ignore politics, cannot fail to be of great benefit both to the medical profession and, as a natural corollary, to the general public.

Correspondence

POST-PUERPERAL POLYNEURITIS

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I have read with considerable interest the article on post-puerperal polyneuritis, by Drs. V. Isvariah and Kutumbiah of Vizagapatam, that appeared on page 13 of your January (1934) issue. The authors of this article and others have reported cases seen by them in the coastal districts of the Northern Circars of the Madras Presidency, which districts have been known for many years past as endemic areas of beri-beri.

About 15 cases of post-puerperal polyneuritis have been admitted within the last 15 months as in-patients in the Railway General Hospital at Lallaguda, a suburb of the city of Hyderabad, Deccan. Hyderabad has not been known as an endemic area of beri-beri, nor has any case of post-puerperal polyneuritis from Hyderabad been reported in the *Indian Medical Gazette*.

This disease generally commences about the second month after delivery with numbness and tingling in the lower extremities; the patients are unable to walk, the calf muscles are tender, the deep reflexes are always absent, and there is flaccidity and wasting in some cases. The sensations were affected in a few cases, but the bladder and rectum were normal, and there was no albumin in the urine. In a few cases the upper extremities were also affected. Lately, we had a fatal case of post-puerperal polyneuritis with mitral incompetence.

A point of very great interest to be noted is that not even a single woman later than six months after delivery was admitted into this hospital for polyneuritis during the period under report.

It was sometimes thought that this disease might have been caused by some medicine, such as mercury or arsenic, given by quacks during the puerperium, but a careful enquiry from the patients failed generally to elicit such a cause. This disease affected usually ill-nourished young Indian women. With nourishing diet, germinating gram, and potassium iodide these patients were cured or improved considerably within two to three months. In cases where there is definite history of syphilis, anti-syphilitic treatment has given rapid improvement.

I am grateful to Dr. B. V. Pulla Reddy, our Acting Chief Medical Officer, for permitting me to refer to the cases treated in the Railway General Hospital.—Yours, etc.

I. VENKATAPAYYA,
Sub-Assistant Surgeon.

RAILWAY GENERAL HOSPITAL, LALLAGUDA,
SECUNDERABAD, DECCAN,
9th February, 1934.

FEVERS IN PREGNANCY

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—It has been brought to my notice that, in my article on 'Fevers in Pregnancy' which you kindly published in the November 1933 number of your *Gazette*, in lines 8 and 9, second column, page 621, I have referred to Glucose 'D' (Sandoz). This is a mistake, in that Glucose 'D' is not a 'Sandoz' preparation. It is a product of the Glaxo Laboratories.—Yours, etc.

M. SARKAR, B.A., M.B., F.R.C.S.E.,
Second Professor of Midwifery and
Second Surgeon.

EDEN HOSPITAL, MEDICAL COLLEGE,
CALCUTTA,
6th March, 1934.

PLANOCAINE IN SPINAL ANALGESIA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In reply to Mr. Surti's letter in the February issue of the *Indian Medical Gazette*, we have to say that we have used one per cent planocaine solution for spinal analgesia for the last two years for all operations, both major and minor, with such good results that in not a single instance has there been a failure in anaesthesia. Regarding the use of percain, we plead inability to express an opinion as we have no experience of this drug. Our reluctance to use percain is the waste of time entailed in keeping the patient in the prone position for ten minutes after injection.

With planocaine the patient is ready for operation while being draped in three minutes after injection. Acute dilation of the stomach was met with in a few cases in the early days when we were using large doses of planocaine for upper abdominal work. Since the introduction of graded dosage for various levels, as detailed in our article in the *Indian Medical Gazette* of September 1933, this complication has not been met with. We should like to quote Dr. F. W. Marwin, M.D., whose article on the 'Present Status of Various Spinal Anaesthetics and their Clinical Usefulness' in the *Journal of the American Medical Association* of 4th November, 1933, which you have extracted in the *Gazette* for February 1934, page 103. He says: 'The use of spinal anaesthesia requires a precise technique for unique results. I strongly advise everyone to employ his own technique in his own clinic. Not every new method that comes along should be adopted. If an anaesthetist has good results, he should continue his technique but, on the other hand, he should not be contented to squat and ignore the newer and better preparations with the improved methods of application'.

We feel that this sums up our attitude towards the usage which we have found most satisfactory in every way.

Regarding the mention of a firm's name in relation to the drug employed (which was not criticized in Mr. Surti's communication) the usual disclaimer is appended.—Yours, etc.

J. F. ROBINSON.
T. SESHACHALAM.

MYSORE, S. INDIA,
1st March, 1934.

Service Notes

APPOINTMENTS AND TRANSFERS

IN pursuance of the provisions of sub-rule (2) of rule 26 of the Council of State Electoral Rules, the Governor-General is pleased to nominate Major-General C. A. Sprawson, C.I.E., K.H.P., being an official, to be a Member of the said Council of State.

IN pursuance of the proviso to sub-section (2) of section 3 of the Indian Medical Council Act, 1933 (XXVII of 1933), the Governor-General in Council is pleased to nominate Major-General C. A. Sprawson, C.I.E., K.H.P., Director-General, Indian Medical Service, as the President of the Medical Council of India.

Lieut.-Col. H. E. Shortt, an officer of the Medical Research Department, is appointed to officiate as Director, Central Research Institute, Kasauli, during the absence on leave of Lieut.-Col. J. Taylor, D.S.O., with effect from the date on which he assumes charge of his duties.

Lieut.-Col. B. Gale, Civil Surgeon, Simla East, was appointed to hold charge of the duties of the Medical Officer of Health, Simla, in addition to his own duties, with effect from the forenoon of the 17th November, 1933, until further orders.

Under rule I (41) of the Rules and Regulations of the Imperial Council of Agricultural Research, the Indian Research Fund Association has elected Lieut.-Col. A. J. H. Russell, C.B.E., to be its representative on the Imperial Council of Agricultural Research, *vice* Major-General J. D. Graham, C.B., C.I.E., K.H.S., resigned.

Lieut.-Col. K. G. Gharpurey, Civil Surgeon, Belgaum, is appointed to officiate as Surgeon-General with the Government of Bombay during the absence on leave of Major-General H. R. Nutt, V.H.S.

Lieut.-Col. K. S. Thakur, Civil Surgeon, Howrah, is appointed as Civil Surgeon, 24-Parganas, *vice* Lieut.-Col. A. Denham White.

Lieut.-Col. M. Das made over charge of the Midnapore Central Jail to Capt. R. Linton on the afternoon of the 7th February, 1934.

Lieut.-Col. E. H. V. Hodge, Civil Surgeon, Dacca, is appointed to act as Professor of Medicine, Medical College, and First Physician, Medical College Hospital, Calcutta, *vice* Lieut.-Col. J. D. Sandes, granted leave.

In partial modification of previous notification His Excellency the Governor of Bengal has been pleased to appoint Lieut.-Col. E. H. V. Hodge, Officiating Professor of Medicine, Medical College, Calcutta, to be Honorary Physician to His Excellency, during the absence, on leave, of Lieut.-Col. J. D. Sandes.

The following persons have been duly nominated under clause (a) of sub-section (1) of section 3 of the Act as members of the Medical Council of India constituted under section 3 of the Indian Medical Council Act, 1933 :—

1. Lieut.-Col. C. Newcomb, Chemical Examiner, Madras, and Professor of Chemistry, Medical College, Madras.

2. Major S. L. Bhatia, M.C., Dean of the Grant Medical College, Bombay.

3. Colonel A. H. Proctor, D.S.O., V.H.S., Inspector-General of Civil Hospitals, U. P.

4. Colonel C. H. Reinhold, M.C., Inspector-General of Civil Hospitals, Punjab.

5. Lieut.-Col. P. S. Mills, Civil Surgeon, Ranchi.

6. Colonel K. V. Kukday, C.I.E. (retd.), (from the C. P.).

7. Colonel J. P. Cameron, C.S.I., C.I.E., V.H.S., Inspector-General of Civil Hospitals and Prisons, Assam.

Major T. H. Thomas, Civil Surgeon, Mymensingh, is appointed, until further orders, as Civil Surgeon, Dacca, *vice* Lieut.-Col. E. H. V. Hodge.

The services of Major W. J. Webster, M.C., an officer of the Medical Research Department, are placed temporarily at the disposal of the Government of Madras for appointment as Officiating Assistant Director, King Institute, Guindy, with effect from the date on which he assumes charge of his duties.

Major G. C. Maitra is placed on foreign service under the Association of the Pasteur Institute of India, Kasauli, for appointment as Director of that Institute, with effect from the date on which he assumes charge of his duties.

Major R. C. Wats is appointed temporarily to the Medical Research Department and is placed on foreign service under the Indian Research Fund Association with effect from the date on which he assumes charge of his duties.

Major J. G. Bird, an Officiating Agency Surgeon, is confirmed as an Agency Surgeon under the Government of India in the Foreign and Political Departments.

Captain H. S. Waters, Officiating Resident Medical Officer, St. George's Hospital, Bombay, is placed in charge of the post of Superintendent of the Hospital in addition to his own duties, as a temporary measure, pending further orders.

Captain H. S. Waters is appointed to officiate as Professor of Midwifery and Gynaecology, Grant Medical College, and Superintendent, Bai Motlibai and Sir D. M. Petit Hospitals, Bombay, during the absence on leave of Lieut.-Col. W. C. Spackman.

The services of Captain D. M. Fraser are placed temporarily at the disposal of the Government of U. P. with effect from the 22nd January, 1934.

LEAVE

Lieut.-Col. J. Taylor, D.S.O., Director, Central Research Institute, Kasauli, is granted combined leave for seven months, with effect from the 20th March, 1934, or subsequent date from which he may avail himself of it.

Lieut.-Col. W. C. Spackman, Superintendent, Bai Motlibai and Petit Hospitals, Bombay, and Professor of Midwifery and Gynaecology, Grant Medical College, Bombay, is granted leave on average pay for eight

months followed by leave on half average pay for four days, with effect from 13th May, 1934, or subsequent date of relief.

Lieut.-Col. W. L. Harnett, C.I.E., Professor of Surgery, Medical College, and Surgeon to the Medical College Hospitals, Calcutta, is allowed leave for the period from the 24th March or date of availing to the 6th June, 1934.

Lieut.-Col. C. A. Godson, Civil Surgeon, Hooghly, is allowed leave for seven months, with effect from the date of relief.

Lieut.-Col. J. D. Sandes, Professor of Medicine, Medical College, and First Physician, Medical College Hospital, Calcutta, is allowed leave for eight months, with effect from the 5th March, 1934, or the date of availing.

PROMOTIONS

Lieut.-Col. to be Colonel

N. M. Wilson, O.B.E. Dated 7th November, 1933. With seniority 1st August, 1928.

Majors to be Lieut.-Colonels

N. D. Puri. Dated 31st January, 1934.

J. B. Vaidya. Dated 31st January, 1934.

To be Captain (on probation)

P. V. Karamchandani. Dated 13th January, 1933. With seniority 26th February, 1925.

(Previous notifications, in so far as they relate to this officer, are cancelled.)

RETIREMENTS

The undermentioned officers retire :—

Lieut.-Col. A. Kennedy, 5th January, 1934.

Lieut.-Col. G. G. Hirst, 24th January, 1934.

RESIGNATION

Captain J. H. Crawford resigns his commission, 2nd September, 1933.

Notes

PHILIPS' X-RAY EXHIBITION IN PARIS

PHILIPS' new demonstration hall for x-ray apparatus was officially inaugurated last week in Paris, the ceremony being attended by a large number of French radiologists.

The French scientists were very keenly interested in the functioning and application of the various types of 'Metalix' x-ray apparatus. The pioneering work that has been done in Philips' laboratories in constructing x-ray tubes giving complete protection against the harmful effect of x-rays, was fully appreciated by the French physicians, who were also very favourably impressed by the high degree of technical perfection attained in the construction of these apparatus.

Special interest was roused by 'Rotalix' tubes ('Metalix' tubes with a rotating anode) which render it possible to take radiograms with a very short exposure time (down to three-hundredths of a second), giving a very sharply-defined picture which is of great diagnostic value.

Visitors also expressed admiration for the various types of x-ray apparatus designed for other purposes, such as for instance the small dental apparatus, which enables dentists to carry out their diagnosis in a very few minutes, and the apparatus for material testing, which is finding more and more widespread adoption in industrial establishments.

COMPLIGON

NUMEROUS vaccines for the treatment of gonorrhoea have made their appearance, without, however, effecting any real progress in the therapy of gonorrhoeal complications. Auto-vaccines, as well as the recently recommended living vaccines, are regarded by some authors as an advance in this direction.

Compligon, as prepared for the first time by Pieper and Wolfenstein and introduced into therapy by them, represents a new and important advance in this field of medicine.

Compligon is not a vaccine but a bacteria-free toxin manufactured by a patented process. It contains the metabolic products which are excreted during the life of the gonococci (exotoxins) as well as the body substances liberated when they are killed (endotoxins).

The choice of our particular culture medium excludes the danger of anaphylaxis since no extraneous proteins are present. *Compligon* is free from corpuscular components (bacterial cells). As a consequence the preparation does not deteriorate with age, as do vaccines by autolysis of the bacteria they contain. Accordingly it has always the character of a fresh vaccine. The preparation is stable to such an extent that it undergoes no alteration whatsoever even if subjected to a temperature of 60°C. for weeks, or heated up to 100°C. for several hours at a time. *Compligon* is thus particularly suitable for the specific treatment of gonorrhœa in the tropics.

Compligon is a light-yellow, weakly-alkaline liquid, either clear or slightly opalescent and contains 0.5 per cent carbolic acid to ensure sterility.

Clinical indications.—*Compligon* is primarily indicated for the specific treatment of gonorrhœal complications in men and women. It has proved particularly valuable in adnexial and general diseases of gonorrhœal origin, for instance gonococcal arthritis.

In their first publication, in which the theoretical bacteriological foundation of *Compligon* was discussed, Pieper and Wolfenstein also reported on 35 cases of gonorrhœal complications in the male which were treated with *Compligon*. On the basis of experience extending over a number of years they have come to the conclusion that treatment with *Compligon* is by far superior to the previous therapy with vaccines.

COW AND GATE MILK FOOD

THE remarkable series of successes gained by that well-known product 'Cow and Gate Milk Food' have been increased recently by an additional *Gold Medal* which was awarded in October at the Mysore Dasara Exhibition. Over 100,000 people visited the exhibition, including members of His Highness the Maharajah's family, many state officials, and visitors from as far away as Bombay and Delhi. The awards were distributed by the Dewan of Mysore.

It will be recollected that this infants' food also gained a gold medal earlier in the year at the 'All-India Sanitary and Scientific Exhibition'.

In the last few years 'Cow and Gate Milk Food' has gained a firm hold on the affections of mothers throughout India, and that this preference is based on very solid and scientific grounds is evidenced by the increasing prescription and recommendation of the food by the medical profession and the grant of honours such as has just been described.

THE MARMITE FOOD EXTRACT

FROM the clinical point of view the significance of the discovery of the hæmatopoietic properties of marmite is obvious. From the theoretical aspect, namely, the study of the ætiology of anæmias, the discovery is also an advance.

According to the theory postulated by Strauss and Castle (*Lancet*, 16th July, 1932, p. 111), normal hæmatopoiesis is dependent upon the interaction of an intrinsic factor present in healthy human gastric juice, and an extrinsic factor supplied by certain food materials. Hyperchromic anæmias are considered to be due to a deficiency of this product of reaction—a deficiency which may be caused by lack of either intrinsic or extrinsic factor or by inability to utilize the fully-formed product.

Work on the ætiology of the anæmias has centred round this hypothesis for some time, with the result that it is generally conceded that some macrocytic

anæmias may be cured simply by supplying sufficient extrinsic factor, whereas in other anæmias notably in Addisonian pernicious anæmia, there is also a deficiency of intrinsic factor, and cure is only possible if the complete hæmatopoietic factor is supplied.

From the study of the hæmatological picture in cases which are considered to require only the extrinsic factor, marmite therapy has without doubt proved effective, and it seems justifiable to assume that marmite is one source of the extrinsic factor.

In view of the fact that certain cases of pernicious-like anæmia have been shown to respond to marmite in adequate doses, some authorities have gone so far as to suggest that marmite, in common with liver, contains the fully-formed hæmatopoietic factor, the exact nature of which still remains obscure, though their views have not received universal acceptance.

The special applicability of marmite—whether used as a medicine or as a food—in India and in other tropical countries deserves mention. It is noteworthy that the anti-anæmic properties of marmite were first discovered in India. That there is urgent need for improvement in the diet of the Indian people is stressed repeatedly by McCarrison ('Problems of Nutrition in India', *Nutrition Abstracts and Reviews*, July 1932, p. 1) and others. Avitaminosis B and anæmias are perhaps even more prevalent in India than at home and this in itself is sufficient reason for the wide use of marmite.

A further explanation for the great demand for marmite in India is found in the fact that it is purely vegetable in origin and may therefore be taken with impunity by all those who, for religious or other reasons, insist upon a strictly vegetarian diet. Another point of practical importance is that marmite is economical in use and is not affected by climatic conditions.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Rs. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

A STUDY OF VITAMIN-A DEFICIENCY IN CEYLON WITH SPECIAL REFERENCE TO THE STATISTICAL INCIDENCE OF PHRYNODERMA AND 'SORE MOUTH'

By LUCIUS NICHOLLS, M.D., B.C., B.A. (Cantab.)
Director of the Bacteriological Institute, Ceylon

THE principal aim in life of the poorer classes of Asia appears to be the production of a family; they multiply to an extent that is only limited by the available food supply; and the spectre of starvation is never far away. Their diets consist of some staple comestible, such as rice, and vegetables; and these may or may not be augmented by a small quantity of dried or fresh fish, and on rare occasions by curds or meat. The fat-soluble vitamins are present in quantities in the more expensive comestibles of animal origin, such as eggs, milk, butter and liver, which these indigent people cannot afford; vitamin A also occurs in green leaves and certain vegetables procurable in quantity only in season.

Therefore it might be expected that signs of the deficiencies of the fat-soluble vitamins should be rife among them, especially in those parts where the dry season spreads over many months each year, when fresh vegetables become unprocurable.

Dr. L. J. Harris (1933) states:—'Recent official reports show that no less than 80 to 90 per cent of the elementary school population of London gave evidence to having had to some degree rickets, notwithstanding the decreasing severity of the disease as now met with'.

The diet of these London school children is incomparably better than that of the majority of the children of the masses of Asia, where 10 cents (2 pence) a day is a reasonable estimate of the cost to the parents of bringing up a child. Yet over 5,000 school children in Ceylon have been inspected recently, and the bone changes of rickets were found in only one of them. Rickets occasionally occurs in Ceylonese children soon after they are weaned, and usually each case has followed some illness which has caused the child to be confined for a long time in a dark dwelling; and the common termination is not recovery, but death.

Although the fat-soluble vitamins are deficient in the diets of the poorer classes of Ceylon, fortunately for the children vitamin D, a lack of which causes rickets, can be elaborated in the body by exposure to the sun, and those of school age must obtain an ample supply in this way. But vitamin A is another matter; it must be supplied ready formed, or

as the provitamin, carotene, in the food. Hawk and Bergeim (1931) sum up the effects of vitamin-A deficiency as 'due to a generalized disturbance of the metabolism of epithelial tissue'.

When albino rats are supplied with a diet lacking vitamin A, but sufficient in other respects, the principal changes that take place in them may be summarized as:—

(a) Eyes—The outer layers of the cornea undergo necrosis.

(b) Alimentary canal—The cells of the salivary glands degenerate, the epithelium of the ducts proliferates and the lumen becomes partly occluded. The mucous-secreting cells of the intestines are atrophied and the tips of the villi are necrosed.

(c) The upper respiratory tract, particularly the nasal passages, the trachea, and bronchi, shows transformation of the lining epithelium into a stratified epithelium of flattened cells, which undergo keratinization.

Therefore the signs of vitamin-A deficiency in man should be sought by an examination of the epithelial tissues.

In a recent paper (1933) I have described a skin eruption, which is prevalent among the prisoners in the jails of Ceylon. The eruption is frequently accompanied by keratomalacia, nerve symptoms, and a decreased resistance to dysentery; and evidence was brought forward to show that it is due to vitamin-A deficiency. I proposed the name phrynoderma (toad skin) for this condition. When the prisoners were being inspected for phrynoderma many of them complained of soreness of their mouths; but at that time these complaints were ignored, and the importance of this mouth symptom was not recognized. More recently a large number of children in schools and adults in jails, asylums, a factory and hospitals have been inspected; and evidence has been forthcoming that not only phrynoderma but also 'sore mouth' is a sign of vitamin-A deficiency; and although there are other results of this deficiency, such as keratomalacia, nerve symptoms and a lowered resistance to infections, these two are the most frequent signs, and a statistical examination for them among the various sections and classes in a community will show the relative degrees of this deficiency.

It is necessary when collecting statistics of the incidence of such symptoms to work to fairly definite standards, so that one observer should obtain results that are comparable to those obtained by another observer.

STANDARDS OF EXAMINATION

Phrynoderma.—This is a papular skin eruption, due to the blocking of the ducts and enlargement of the sebaceous glands. (It is comparable with the changes which take place in the salivary glands of rats which have been fed on a diet lacking vitamin A). This eruption is sometimes accompanied by a dryness and scalliness of the skin.

The eruption occurs most commonly on the extensor surfaces of the arms and legs (*vide* plate III, figs. 1, 2, 3, 4 and 5); it may occur on any part of the body, but it is not common on the face, neck, hands and feet.

The eruption ranges from a just-perceptible enlargement of the sebaceous glands on the extensor surfaces of the arms to marked enlargement of these glands over the greater part of the body.

The following standards have been adopted :

(1) There must be perceptible enlargement of the glands on the extensor surface of one or both arms. This situation is adopted for these reasons:

(a) The enlargement of the glands on other parts of the body without enlargement of the glands on the extensor surfaces of the arms occurs among Ceylonese in only about 2 per cent of cases, and this will not materially affect the statistics of prevalence.

(b) It is the easiest situation of the body to examine in persons wearing clothes.

(c) The examination of the legs, etc., of women and girls must be avoided.

(2) The enlarged glands must be palpable.

(3) When the glands over and for three inches below the olecranon process show slight and uniform enlargement, and there is no enlargement of the glands of the arm above and below this situation, the case is recorded as negative. But when these glands over and for three inches below the olecranon process show slight uniform enlargement, and more than two of them show marked enlargement such as is shown by the glands in figure 3 of plate III the case is recorded as positive.

'Sore mouth'.—The standard adopted has been patches of superficial erosion of the mucous membrane of the tongue or lower lip, or its later stages, when the tongue becomes red and glazed. These patches are red and are in marked contrast to the unaffected parts of the tongue which show the whitish *duvet* of the slight normal fur. Some children with sore mouths have excoriation and ulceration of the angles of the mouth, as shown in plate IV, fig. 8. But when they have this condition without signs of erosion of the mucous membrane of the tongue or lower lip they are considered negative.

These standards for phrynoderma and sore mouth may be somewhat arbitrary, but without such standards many doubtful cases would be included in the statistics.

THE INCIDENCE OF PHRYNODERMA AND 'SORE MOUTH'

Schools.—There are several hundred schools and colleges in Ceylon and these may be divided into three classes :—

(a) Vernacular schools, where free education in the vernacular language is given to the poorest classes.

(b) English schools, where small fees are charged for an education in English and the vernacular languages; the children of these schools may be considered to belong to the middle class.

(c) College schools, where the standard of education is much the same as in the best class schools in England. The children of the upper class Ceylonese attend these schools.

Table I shows the incidence of phrynoderma in schools :—

TABLE I

	Number of children examined	Number positive for phrynoderma	Percentage positive
Colombo vernacular schools.	1,164	335	28.7
Vernacular schools along south-west coast road.	2,628	768	29.2
Deaf and blind school.	307	71	23.1
English schools along south-west coast road.	219	39	17.7
Colombo English schools.	353	55	15.5
Colombo college school boarders.	136	4	2.8
Youths in industrial department of the deaf and blind school.	26	0	..
A charity boarding school for destitute children.	47	39	83.0

After the importance of 'sore mouth' had been recognized all children were inspected for phrynoderma and sore mouth.

Table II shows the incidence of sore mouth in the schools :—

TABLE II

	Number of children examined	Number positive for sore mouth	Percentage positive
Colombo vernacular schools.	831	80	9.6
Vernacular schools along south-west coast road.	2,628	204	7.7
English schools along south-west coast road	219	12	5.5
Colombo English schools.	353	30	8.4
Colombo college school boarders	136	0	..
A charity boarding school for destitute children.	47	13	29.2

The workmen in an engineering factory.—The workers in the factory in question were all men. Owing to the depression they were working for three days a week only, and the

Fig. 6.

Fig. 7.

Fig. 8.

Fig. 9.

average pay of each man was Re. 1.50 a day. Table III shows the result of the inspection:—

TABLE III

	Number inspected	Number positive for phryno-derma
Men working in the foundry	23	0
Men working in the black-smith shop.	31	1 (slight)
Men working in the machine shop.	40	1 (marked) 1 (slight)
Men working in the bridge shop.	67	0
Men working in the carpenter's shop.	31	1 (slight)
Men working in the boiler house.	3	0
	195	4

This gives a sufficiently accurate normal standard for comparison with other groups of adults.

Patients in a mental asylum.—A very interesting state of affairs was found at a mental asylum. The medical superintendent lined up for inspection 132 Ceylonese patients on Ceylonese diet, and in the same court-yard lined up 48 Ceylonese patients on European diet so called. Then 100 women on Ceylonese diet and 33 on European diet were inspected.

Table IV shows the results:—

TABLE IV

	Number examined	Number positive for phryno-derma	Percentage
Men on Ceylonese diet.	132	58	43.8
Men on European diet.	48	1	2.0
Women on Ceylonese diet.	100	44	44.0
Women on European diet.	33	1 (a recent admission)	..

The contrast between the skins of those on these two classes of diet was very striking and a biological experiment could scarcely have been better arranged.

These diets will be discussed later in this paper.

The male section of the asylum is somewhat overcrowded but the female section is not.

Patients in a leper asylum.—Two hundred and thirty-four male patients were examined in a leper asylum, and only one patient was markedly positive for phrynodermia, and the appearance of it suggested that the eruption

was clearing up. He had nerve leprosy, and his history was that he had been in the leper asylum for 5 months and was discharged; he returned after 1½ years; during this time he was poverty-stricken; he had been in for 3 weeks since readmission. Three patients who had been in for 4 months or less showed slight signs. But one patient who had been in for 4 years showed slight signs.

The leper asylum is overcrowded, there are 505 beds and 678 patients, so that 173 patients must sleep on mats where they can find room to place them. This overcrowding was very marked in a temporary building which has a *kadjan* roof and a cow-dung floor. There were 67 patients in this building but none had signs of phrynodermia. This indicates that overcrowding does not affect the incidence of this eruption.

A tuberculosis sanatorium.—Only five cases of phrynodermia have been discovered among over a hundred patients, who had been in various hospitals for a month or more, and were receiving presumably a diet adequate in vitamin A. Three of these patients were suffering from advanced abdominal tuberculosis.

(The fourth case was of a woman where the diagnosis was neuritis. Her history indicated that she had had advanced phrynodermia and neuritis and had nearly died. The fifth case was of a deaf, dumb and blind cripple who had been in hospital for 11 years; he was in a state of extreme infantilism, probably of the Lorain type, in which the pituitary gland has failed to develop. This is interesting because of the possible interrelation between hormones and vitamins.)

The existence of phrynodermia in the tuberculous patients suggested that the increased metabolism of the body to tuberculosis might call for a greater supply of vitamins than are necessary for a healthy person. This would make the treatment of tuberculosis patients with large doses of cod-liver oil less empirical than heretofore. Therefore a tuberculosis sanatorium was inspected, and table V shows the results:—

TABLE V

	Number examined	Number positive for phryno-derma
Men ..	102	6
Women ..	75	5

Five of the six men, who had phrynodermia, had been in the sanatorium for less than one month, and none of the six had received cod-liver oil.

Four of the five women, who had phrynodermia, had been admitted during the previous

fortnight and the fifth had been in for two months; none of them had received cod-liver oil.

The diet of the patients includes milk and butter, and, because phrynoderma occurs among those recently admitted and is almost absent among the older residents, it is concluded that the diet is adequate in vitamin A.

Jails.—In a previous paper (Nicholls, 1933) it was recorded that the prisoners, who had been imprisoned in a certain jail for one month or less, were relatively free from phrynoderma; that this skin condition was very prevalent among those who had been in for periods up to $1\frac{1}{2}$ years; and that there was a small lessening of this prevalence among the residents who had been in jail for more than $1\frac{1}{2}$ years. Since that paper was written many more prisoners in other jails have been inspected with very similar results. The prisoners can be divided into two categories for the purpose of a brief table in this paper:—

Category I, those who have been in prison for one month or less.

Category II, those who have been in prison for more than one month.

TABLE VI

	Number examined	Number positive for phrynoderma	Percentage positive
Category I ..	420	44	10.4
Category II ..	928	508	54.7

I have inspected for sore mouth the prisoners of only one jail—the Southern Province Jail, which has a reputation of being a healthy jail; it is exceptional in that only local prisoners that have been sentenced to six months or less are retained; and as most of them earn remissions from their sentences, only six of them had been in for more than five months.

Table VII gives the results of the inspection:—

TABLE VII

	Number examined	Number positive for phrynoderma	Per cent positive for phrynoderma	Number positive for sore mouth	Per cent positive for sore mouth
Ramnad Jail.	50	5	10	1	..
2 weeks or under.	54	6	11.1		
2 weeks to one month.	33	5	15.1		
Over one month.	58	21	36.2	12	20.6

The increase in prevalence of phrynoderma in these prisoners after they have been in for more than one month, although less, is similar to that for other jails in Ceylon. And sore mouth which is almost absent among the new arrivals becomes prevalent among the old residents. There were two cases of keratomalacia among the prisoners who had been in for more than one month.

The Quarry Jail is 80 miles distant from the Southern Province Jail, and had been inspected before the importance of 'sore mouth' was realized. I was accompanied on the day of my inspection by Dr. G. W. Bartholomeusz, the medical officer of the jail. Two hundred prisoners were examined and the incidence of phrynoderma was 38.5 per cent.

Some time after this inspection I wrote to Dr. Bartholomeusz asking him to make a survey of the prison for phrynoderma, neuritis, keratomalacia, diarrhoea or dysentery, and 'sore mouth'. I had not discussed standards with him and therefore his investigation was independent, apart from the fact that I had shown him a number of cases of phrynoderma.

He has supplied me with tabulated details of each prisoner with phrynoderma; these are summarized as follows:—

He found that 231 prisoners out of a total of 923 in the jail had phrynoderma. This is a percentage of 25.0; which is lower than the percentage in my determinations among a smaller number of these prisoners. It may be that he included only the more marked cases.

The other signs of vitamin deficiency among these prisoners he found as follows:—

TABLE VIII

	Number	Percentage
Neuritis	19	8.2
Keratomalacia	22	9.5
Diarrhoea or dysentery since imprisonment.	62	26.8
'Sore mouth'	103	44.5

Dr. Bartholomeusz states that the diagnosis of 'sore mouth' was founded on 'glazed raw red tongues in varying degrees'.

The name of each prisoner and the time he had been in jail is stated in his tables and from this the prisoners may be divided into two categories:—

Category I, those who have been in for one month and less than 6 months.

Category II, those who have been in for more than 6 months.

The results are shown in table IX :—

TABLE IX

	Number of prisoners with phrynoderma	Number of prisoners with sore mouth and phrynoderma	Percentage
* Category I ..	80	23	26.2
Category II ..	150	80	53.6

* One prisoner is excluded as he had been in prison for a few days only.

This shows that 'sore mouth' is twice as prevalent among the prisoners that had been in jail for more than six months.

Dr. Bartholomeusz did not investigate the incidence of sore mouth among all the prisoners, but confirmed his attention to those with phrynoderma. There were 37 cases of phrynoderma and 13 cases of sore mouth in the Southern Province Jail (*vide* table VII); but three prisoners with sore mouth did not show signs of phrynoderma. Therefore 10 cases out of 37, which would fall into category I of table IX, give a percentage of 27, which is nearly the same as 26.2 of table IX. Perhaps such closely approximate results were hardly to be expected from two observers examining prisoners in jails over 80 miles apart, but the figures for the Southern Province Jail are small.

Dr. Subramaniam, the medical officer of another jail, was asked to investigate the number of prisoners with marked signs of sore mouth and to give the date of admission and the duration of the sore mouth in each case.

He has forwarded these records for 47 prisoners, and table X gives the analysis of these :—

TABLE X

Those who had sore mouth on admission	4
Those who acquired it within three months of admission.	0
Those who acquired it between 3rd and 6th month after admission.	10
Those who acquired it more than 6 months after admission.	33

—
47

There were 616 prisoners in the jail at the time of inspection and 126 had been in for less than 3 months.

THE RELATIVE INCIDENCES BETWEEN PHRYNODERMA AND 'SORE MOUTH'

Table I shows that the incidence of phrynoderma is greater in the schools of the poorest classes than in the schools for the better classes. Table II shows that the incidence of sore mouth is similar in this respect; but the two

conditions do not follow one another in uniform curves; for instance the incidence of phrynoderma is greater and the incidence of sore mouth is less in the Colombo English schools than in the schools along the south-west coast road.

The following tables summarize the results for all the children who have been examined for phrynoderma and 'sore mouth':—

TABLE XI

		Percentage of total
Number examined ..	4,380	..
Negative for phrynoderma ..	3,205	73.1
Positive for phrynoderma ..	1,175	26.8
Positive for phrynoderma and negative for sore mouth.	830	18.9
Positive for phrynoderma and positive for sore mouth.	345	7.7
Negative for phrynoderma and positive for sore mouth.	89	2.1

TABLE XII

	Percentage
The incidence of sore mouth among those with phrynoderma.	29.3
The incidence of phrynoderma among those with sore mouth.	79.4
The percentage absence of phrynoderma among those with sore mouth.	20.5

Table XII shows that the incidence of sore mouth among children with phrynoderma is 29.3 per cent, which is in close agreement with the percentages 27 and 26.2 found among the prisoners of two jails.

If there was no aetiological relationship between phrynoderma and sore mouth, the incidence of phrynoderma among children with sore mouth would be the same as for all the children in the schools, namely 26.8, and not 79.4 as is shown in table XII.

As previously stated there were thirteen prisoners in the Southern Province Jail who had sore mouth and ten of these had phrynoderma, giving a percentage of 81.2, which is in close agreement with the 79.4 percentage for the school children.

DIETS IN CEYLON

Condiments are much used by all classes of Ceylonese; when a preparation of condiments is liquid it is called a curry, and when it is more-or-less solid it is called a sambol.

There is a subtle acidity and pungency in the smell of these preparations, which will cause a flow of saliva and an increase in appetite even in those who seldom partake of them. The use of condiments has been developed for the purposes of dispelling among the poorest classes the anorexia which arises from a deficient food supply; or to stimulate the surfeited appetites of the gourmets among the wealthy.

The following are some of the condiments used in curry making in Ceylon:—

Coriander, anise, dill fruit, pepper, mustard, chillies, saffron, various aromatic leaves, tamarind, cinnamon, onions, garlic, vinegar, cloves, cardamoms and nutmegs. A selection of these are boiled with salt in coconut milk in making the best curries, but the poor must often be content with a watery concoction of chillies, salt, onions and lime juice. All curries and sambols contain lime juice or tamarind.

A knowledge of the diets of the poorer classes is not easily obtained, because they are apt to resent a close inquiry into their intimate affairs; and some will plead poverty, and represent their diet worse than they are, while others will exaggerate the quality of theirs.

Mr. Richard de Silva of this laboratory made an enquiry into the dietary of over 100 children in a vernacular school. They were supplied with writing material and sent home to work out with their parents the composition of every meal that they had had for the past seven days. When these papers were collected and examined it was found that the children had had the usual three meals a day and had mentioned 83 comestibles*. The names of the comestibles may be placed into groups, for instance:—the children mentioned five varieties of hoppers, six varieties of dried fish, and numerous kinds of vegetables most of which fall into one of three groups:—

- (1) Watery vegetables, such as snake gourds and cucumbers.
- (2) Leaf vegetables of which the leaves only are eaten.
- (3) Other vegetables such as plantains and yams.

And thus it was found that their diets consisted of rice, dried fish and small amounts of vegetables daily.

This enquiry was made in September, and had it been made at another season of the year the names of other foods would probably have preponderated in the lists, for instance if bread fruit and jak fruit had been in season, the names of these would have appeared in all the lists.

Two children had received meat at one meal only. No one had had butter or ghee, and only two had had milk. A few of them had tomatoes or sweet potatoes at one or two meals during the week.

The children partake of three meals a day. These are of the following nature:—

(1) *Early-morning meal.* This consists of either cold boiled rice or hoppers eaten with a small quantity of sambol. The commonest kind of hopper is made by kneading ground rice with coconut milk, and roasting it on a hot plate, when its shape resembles that of a thick pancake.

The commonest sambol is made by grinding chillies, salt, onions and a fragment of Maldivian fish between stones, and adding lime juice to the ground mass.

*Tables of the diets of the children and prisoners (v.i.) have been deleted from this paper to economize space.

(2) *The midday meal* consists of boiled rice and a little curried dried fish or vegetables.

(3) *The evening meal* is made from what is left over from the midday meal.

The children only occasionally receive such vegetables as tomatoes, which are fairly rich in vitamin A.

Many tropical vegetables have not been biologically assayed for the vitamin-A content, but by analogy they may be placed in the same categories with other vegetables, which have been assayed.

G. S. Fraps and Ray Treiehler (1933) have published lists giving the Sherman-Munsell rat units for vitamin A in each ounce of various foods.

I have adopted these units in an attempt to estimate the amount of vitamin A in the diets of children and others. When the vitamin-A content of a vegetable is unknown I have assigned to it a much higher number of units than it probably contains. For instance a snake gourd resembles a cucumber in appearance, and gives a very similar analysis (*vide* table XIII); the vitamin-A units in cucumber have been determined as 10 per ounce, but I have allowed 70, which is the same as for pumpkin. The water pumpkin of Ceylon resembles water melon of which the vitamin-A content has been determined as 28, but 70 units per ounce have been allowed. All green leaves have been assigned 410 units, making them of much the same value as spinach of which the vitamin-A content has been determined as 402; and this is the maximum for green leaves which have been assayed, with the possible exception of lettuces.

Manioc and yams are assigned the same value as sweet potatoes.

Table XIII gives the analysis of some of these vegetables and in the penultimate column is shown the vitamin-A units of those vegetables which have been assayed, and in the last column are shown the units per ounce which have been allowed in the calculations of the vitamin-A content in the diets of children, prisoners and others.

It follows that the actual amounts of vitamin A in the diets are probably much lower than the estimated amounts.

Forty-one women were supplied with vegetables and requested to separate those quantities from each of them which they considered would be ample for the daily needs of a child aged 12. These 41 quantities of each vegetable were weighed; the weights varied from 1 ounce to 2½ ounces for green leaf vegetables, and the average was 2 ounces. Similarly for other vegetables such as snake gourd and plantains the average weight was 3 ounces approximately.

These quantities have been used for estimating the number of units of vitamin A in the children's diets. The rice consumed by these children was imported polished rice, which contains little, if any, vitamin A. A small

TABLE XIII

Showing relative composition and vitamin units per ounce of certain vegetables

Vegetable	Water	Protein	Oil	Carbo- hydrate	Fibre	Ash	Vitamin-A units determined	Vitamin-A units allowed
Cucumber	95.4	0.87	0.16	7.87	0.71	0.40	10	10
Snake gourd	94.6	0.63	0.13	4.25	0.13	0.28	..	70
Pumpkin	89.0	1.7	0.7	6.60	1.7	0.60	70	70
Spinach	90.6	2.5	0.5	3.8	0.9	1.7	402	410
Tampala (leaf).	81.4	4.5	0.57	8.4	2.0	3.16	..	410
Kankun (leaf).	89.7	4.25	0.04	3.64	0.7	1.67	..	410
Sweet potatoes.	71.1	1.5	0.4	24.7	1.3	1.0	85	90
Manioc	74.2	1.10	0.18	22.9	1.15	0.52	..	90
Yams	63.7	2.86	0.05	27.31	1.03	1.45	..	90

amount may be present in dried fish and condiments but not enough to affect these estimates materially.

Fraps and Treichler (1933) estimate that 1,000 units per day per person are required by man, woman or child and state:—'This may not be ample for the highest health and vigour, but should be sufficient for growth and maintenance'.

Only one of the children received 1,000 units or more, the daily average was 312 units.

Prison diets.—The kind and quantity of the comestibles in these diets are laid down by law and may not be varied except for prisoners in hospital. There is a penal diet and each prisoner receives boiled polished rice and 4 ounces of a vegetable daily for the first fortnight of imprisonment; during the second fortnight he receives only 2 ounces of a vegetable, but there is added to the diet 2 ounces of plantain and 2 ounces of *dāl*. Thereafter for a year he receives daily the following diet:

	Ounces		
Bread 4
Rice 18
Lean fish 2½
Plantain 2
One vegetable 2
<i>Dāl</i> 2
Sugar ½
Coconut ¼
Lime (juice) ½ (a lime)
Onions ½
Chillies, pepper and salt q.s.

The records of the daily supply of vegetables throughout the year were obtained from the offices of 10 prisons.

The average number of units which have been received in the vegetables daily by the prisoners in the various jails is 162. When 120 units for 2 ounces of plantain, 140 units for 2 ounces of *dāl*, and 100 units for the bread are added, each prisoner received daily 522 units.

The diet of the patients in the mental asylum.

—The Ceylonese diet of the patients is somewhat better than the diets of the prisoners, but not greatly so, as can be shown by the fact that the cost of the daily diet for each patient is only 2½ cents (½ penny) more than the average for each prisoner in the various jails. The 'European' diet costs 10½ cents more than the 'Ceylonese' diet; and the difference in the two diets can be summed up as follows:—

	European diet	Ceylonese diet
Bread	12 ozs.	8 ozs.
Rice	6 "	16 "
Eggs	2 "	nil.
Milk	5 ozs.	nil.

An estimate similar to that made for the prison diets shows that the patients on Ceylonese diet should receive about 620 units of vitamin A daily.

The contents of Ceylon eggs weigh about 1½ ounces. The units in eggs have been shown by assay to be 550 per ounce at the beginning of the laying season and to fall to 170 per ounce at the end of the season. Therefore a conservative estimate of 200 per ounce may be allowed, which is 600 units for two eggs. An equally conservative estimate for milk is 40 units an ounce, which is 200 units for 5 ounces.

Therefore the patients on European diet receive at least 1,400 units daily.

If this is considered with the facts shown in table IV, it follows that the addition of 2 eggs and 5 ounces of milk to a diet is sufficient to prevent phrynoderma.

The diets of the leper asylum and tuberculosis institute.—The diets in these institutions are even more generous than the European diet at the mental asylum; therefore it is not surprising that the older residents are free from phrynoderma.

Diet at the deaf and blind school.—Table I shows that phrynoderma occurred in 23.1 per cent of the children in this school, and that it was not found among 26 youths in the industrial section. The details of the diets have not been obtained, but they have been stated shortly to be as follows:—

	Children	Youths in the industrial section
Rice	A sufficiency	A sufficiency
Vegetable curry	3 ozs.	6 ozs.
Dāl, meat or fish curry	3 "	..
Meat curry	4 ozs.
Fish curry	4 "
Total curries	6 ozs. daily	14 ozs. daily

It follows that the youths probably obtain at least twice as much vitamin A as the children.

Diets of college boarders.—It is sufficient to state that the cost of the diet of the college boarders referred to in tables I and II is three times the cost of the diet of the children in the deaf and blind school.

The diets of a charity boarding school for destitute children.—There is shown in tables I and II a high incidence of phrynoderma and sore mouth in a charity school. Direct and indirect inquiries suggested that the feeding of these destitute children was very bad; but unfortunately actual details could not be obtained. It appeared possible that the children had not recovered from a destitution previous to admission, but this was not so, because there were only eight children among the 47 boarders who were more or less free from phrynoderma, and seven of these had been in the school for less than one month, and the other had been in for two months. And the degree of phrynoderma or sore mouth more or less varied with the length of time that the children had been in the school.

There were in the school 17 children who attended the classes, but lived at home. Four of these had phrynoderma, this gives much the same percentage of prevalence as occurs in other schools in the neighbourhood; but their condition was markedly better than that of the boarders.

This may be a good example of the value of the inspection of school children for phrynoderma and 'sore mouth' as a criterion of the sufficiency of their diets.

Advanced cases of phrynoderma in children.—Four young patients have been seen recently in whom blindness had occurred. One was a child, age 4 years, the right eye was staphylococcal and the left showed opacities from healing corneal ulceration. The child had been unable to walk and at the time of examination

was walking with difficulty, the muscles were wasted, and the feebleness and awkwardness of the arms and legs suggested neuritis. The child had extensive phrynoderma. Two other cases were very similar to this, and both had phrynoderma.

The most advanced case seen was of a boy (age 16) in hospital; his signs and symptoms were:—

(a) General emaciation, but not particularly noticeable in the face.

(b) General phrynoderma of the whole body except the hands, feet and face.

(c) A superficial dermatitis around the eyes and mouth with peeling of the skin (*vide* plate IV, fig. 9).

(d) Right eye—keratomalacia, slight sight. Left eye—commencing staphyloma, blind.

(e) Dermatitis deep seated in auditory meatus. He was very 'hard of hearing'. This deep-seated dermatitis of the ears is not very uncommon in cases of marked phrynoderma.

(f) Neuritis, unable to walk, wrist drop, and absence of knee jerks.

(g) Mental condition—extremely irritable.

(h) There was no erosion of the tongue, but marked erosion of the lower lip.

(i) The temperature had been and was normal.

Advanced cases, in which there are no signs of eye lesions, are fairly common in young indigent children after 6 months of age, that is from about the time when they are weaned; the symptoms are:—extreme emaciation, phrynoderma, sore mouth (in about 60 per cent) and diarrhoea; weakness and wasting of the muscles of the limbs may indicate neuritis. Pyrexia may or may not be present.

THE AETIOLOGY OF BLINDNESS IN CEYLON

Keratomalacia is common in Ceylon; and xerophthalmia keratomalacia, corneal ulceration and staphyloma appear to be the usual sequence leading to blindness.

The lady superintendent of the deaf and blind school has made extracts of the history sheets of all those under her care, which might throw some light on the causes of the blindness (and deafness).

The statements have been placed into the following categories:—

Category I. Those who are recorded as having been blind from birth or shortly after birth.

Category II. Those who presumably have become blind as a result of keratomalacia. The earliest date of blindness after birth for those in this category is stated as three months. The following are the types of statement which have been accepted for placing children in this category:—

'Results of rickets at 3 years'.

'Blindness through malnutrition'.

'Blind through mandama' (marasmus).

'Debility when 5 years old'.

'Disease when 2 years old'.

Category III. Those who are stated to have been blinded as the result of an accident, cataract, smallpox, etc.

Category IV. The history is too indefinite for the first three categories.

Table XIV is the summary of this analysis:—

the patient may not be able to feed himself. But advanced cases are rare except in those who have chronic dysentery. On one occasion

TABLE XIV

		Boys	Per cent	Girls	Per cent	Total	Per cent
Category I	17	20.1	11	16.4	28	19.0
Category II	49	61.2	48	71.6	97	65.9
Category III	7	8.7	1	1.4	8	5.4
Category IV	7	8.7	7	10.4	14	9.5
TOTAL	80	..	67	..	147	..

Therefore it is probable that about two-thirds of the children are blind as the result of keratomalacia following vitamin-A deficiency.

The deafness is another matter. There were 170 deaf and dumb children in the school. And such statements as:—'followed boil on head', 'adenoids and tonsils', 'after pneumonia' suggest that 20 per cent of them had had middle-ear disease. The remaining 80 per cent of the children are reported to have been deaf from birth. The statement by a parent as to the time when a child became blind may be accepted as correct, but deafness is not noticeable as early as blindness.

GENERAL DISCUSSION

The damage to the epithelial structures from vitamin-A deficiency which occurs in experimental animals has its counterpart in man in the form of phrynoderma, 'sore mouth' and keratomalacia.

But the signs and symptoms which follow this deficiency are more variable than those which follow other vitamin deficiencies, such as in scurvy, pellagra or beri-beri.

In Ceylon phrynoderma is the commonest sign, and perhaps it is not astonishing that the sebaceous glands require a fat-soluble vitamin for the elaboration of the oily sebum. 'Sore mouth' is the next in frequency, yet only about 80 per cent of cases of this condition show marked phrynoderma; and patients may have advanced phrynoderma and keratomalacia without 'erosion of the tongue' as in the case of the boy aged 16 mentioned above. Phrynoderma occurs in a high percentage of cases of prisoners with keratomalacia but not in all cases.

The symptom which has been called neuritis in this and a previous paper requires further elucidation as to the nature of the lesion; it may not be a neuritis. In its earliest stages the patient complains of a burning sensation in the palms of the hands and the soles of the feet. This is followed by muscular weakness, later by wasting of the muscles and an atoxic gait, and later still by inability to walk and great weakness in the arms and hands, so that

when the prisoners in a jail hospital were inspected there were 17 patients with chronic dysentery, and all of them had marked signs and symptoms of this 'neuritis'. Morgan (1929) described a condition termed 'burning feet', which is apparently common among indigent Tamil emigrants in Malaya. He treated 19 severe cases in hospital; the diet he gave them was Indian corn, ragi, eggs and mutton. The pain was less in a week and apparently gone in a fortnight. He appears to have attributed some of the improvement to the administration of nitroglycerine. But the hospital diet is the more probable reason of the rapid improvement. Labernadie (1927), in reference to 'burning feet' said that in 1762 it was recorded from Savigliano in Piedmont and in 1806 among troops in Padua; it was called pedionalgia, or chiropodalgia if the hands were also attacked.

The absence of wide recognition of the effects of vitamin-A deficiency in man may be due to the irregularity of the signs and symptoms, and may explain anomalous observations on infections following this deficiency. For instance vitamin A has been called the 'anti-infective' vitamin, and its deficiency in diets has been supposed to increase the liability to epidemic diseases, especially of the respiratory tract. But this has not received universal acceptance.

Damage to the epithelial tissue of the respiratory tract should render a person more liable to bronchitis or pneumonia than a normal person; and it may be that the stresses of a cold climate will determine that the effects of vitamin-A deficiency shall fall first on the respiratory epithelium. Therefore respiratory diseases may follow vitamin-A deficiency under certain climatic conditions.

Similarly a generally poor diet overcharged with stimulating condiments will throw stresses upon the epithelial tissues of the alimentary tract, and there bring out the effects of vitamin-A deficiency and increase the liability to dysentery. The outbreaks of dysentery among the prisoners in the jails of Ceylon are due to infection with Flexner's bacillus following vitamin-A deficiency.

Three post-mortem examinations have been done on adult male prisoners, all of whom had had phrynoderma and dysentery, and two advanced neuritis. There were the usual dysenteric changes in the large intestine, and in two cases the last foot of the ileum was affected.

The livers weighed 30, 31, and 35 ounces, respectively, and had undergone fatty degeneration of moderate degree. The spleens weighed 3, 3½ and 4 ounces, respectively. Two of these subjects were wasted, but the loss of weight of these organs appeared to be out of proportion to the general wasting. The third subject was not wasted, he had had dysentery for one week only. The walls of the small intestine were thinner than normal, and in two cases slight superficial erosion of the epithelium of the mucosa was seen extending from the lower parts of the jejunum to where the ileum had undergone dysenteric changes. This erosion was not marked in the third subject but the villous processes were seen in microscopical sections to have undergone marked atrophy.

The general health of Ceylon school children.—It is difficult during an inspection to gauge the general health of the children. A child may have considerable areas of the skin affected with phrynoderma, and yet appear to be in fair health. Even those with 'sore mouths' do not appear to be greatly affected otherwise. Some of them appear puny and lethargic. Probably those in bad health remain away from school, and this is reflected in the school attendance lists, which show that the number of absentees daily is large. If the effect of vitamin-A deficiency upon the growth of children is to be estimated it must be done by weighing and measuring them.

The high degree of vitamin-D deficiency in London school children may affect the quality of the population but it does not greatly increase the death rate; but the vitamin-A deficiency in Ceylon school children probably does increase the death rate. Table XV shows the death rates per 1,000 in 1931 for England and Ceylon for young persons up to 20 years of age :—

TABLE XV

	England	Ceylon
Under 5 years	20.0	67.1
5 to 10 years	2.1	7.8
10 to 15 years	1.5	3.7
15 to 20 years	2.5	6.8
All ages	10.2	22.1

The dietary in dysentery.—In *Manson's Tropical Diseases* on page 395, where recommendations are made for a diet in dysentery, there appears the statement:—'The best diet is one consisting of jellies, albumen water,

rice water, chicken conje, beef tea, Brand's essence, arrowroot, sago puddings....' All of these are more or less deficient in vitamin A. Similar diets are recommended in all textbooks, and doubtless are appropriate for well-fed persons, who contract dysentery. But such diets are not indicated where there is vitamin-A deficiency. Many native doctors, following the systems of the East, have obtained a reputation for the treatment of dysentery; they use fresh extract of green herbs, and some of them augment these by prescribing strange meats such as the liver of the land tortoise. Success in such treatment may be due to the unconscious administration of vitamin A in a form easily assimilated. And in countries where this vitamin is markedly deficient in the diets of the poorer classes, the administration of preparations of leaves might be of value in almost any disease.

Proprietary foods.—Many foods reinforced with vitamin D have been placed on the market. These foods are of much value in Europe, especially in towns where the atmosphere is smoke-laden, and the children seldom enjoy sunlight during the winter months. But the food which is indicated for the tropics of the East is one which has been reinforced with vitamin A*.

The knowledge of vitamins.—The acquisition of the knowledge of vitamins started clinically, by scurvy, pellagra, and beri-beri being vaguely attributed to faulty diets. Once animal experiments were initiated the knowledge became more definite. And the science of dietetics could never have been built upon sound foundations without these experiments. But there has developed too great a tendency to apply without modifications the results of deficient diets in animals to the dietary of man.

An example of this is shown in the work of Jansen and Donath (1925) in the Dutch East Indies; when reasoning from experiments on rats these authors concluded that the use of one banana a day will prevent A-avitaminosis in those living upon a rice diet.

The vitamin requirements of one species of animal are not necessarily the same as those of another. For instance albino rats cannot be used in the biological assay for vitamin C, because either this vitamin is synthesized by rats, or they require very small amounts of it.

Laboratory animals lead sedentary and protected lives free from the activities and stresses which wild animals must experience, and this will affect their vitamin requirements. The accessory food factors in a comestible may be determined by animal experiments; but the relative requirements for a caged rat and a hard-working labourer cannot be defined accurately by such experiments. The amount of a vitamin necessary to maintain health varies with the nature of the other components

*and vitamin B we should add.—Error, I. M. G.

in a diet; and may be more for a diet rich in carbohydrates than for one rich in proteins.

A wide field for inquiry exists in the homes of the destitute, the prisons, the asylums, schools, slums and villages of the East by those who have had experience in the signs and symptoms of food deficiencies. Because experiments, almost equal to those of the biochemist, are occurring fortuitously.

The knowledge of human dietetics will be enhanced by such investigations; and the time will come when the number of units of vitamins necessary to maintain health on various diets will be determined as accurately as in the estimation of the caloric units of other components of a diet.

It is possible that phrynoderma is a common condition in other countries, and doubtless has been described on many occasions without its significance being recognized. Malcolm Morris (1917) appears to refer to it under the term xeroderma. Chalmers Watson (1904) describes xeroderma affecting a boy aged 6; he appears to attribute the disease to malnutrition, and mentions the changes in the sebaceous glands, the boy was cured by inunctions of myelocenc and the administration of cod-liver oil.

The condition may have been referred to under such terms as keratosis pilaris, pityriasis pilaris, lichen pilaris, or keratosis suprafollicularis.

Since the work described in this paper was completed there has appeared in the *Archives of Dermatology and Syphilology* a paper by Dr. L. J. A. Loewenthal (1933) wherein he describes a similar dermatosis occurring among the prisoners of the East African jails; he attributes it to a deficiency of vitamin A in the diets. He does not give any definite name to the eruption; but mentions that Dr. A. Pillat described a somewhat similar eruption in 1929.

Therefore it appears that either Dr. Loewenthal or Dr. A. Pillat have priority in attributing this type of dermatosis to vitamin-A deficiency.

DYSENTERY PRODUCED BY BACTERIUM PSEUDO-CAROLINUS

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

and

R. N. CHAUDHURI, M.B. (Cal.)

School of Tropical Medicine, Calcutta

BACILLARY dysentery occurs quite commonly in Calcutta. A routine examination of stools in the School of Tropical Medicine, Calcutta, has shown an incidence of bacillary dysentery in 12.5 per cent of the total admission of cases during the year 1933. During the last few years, however, a large number of cases of subacute and chronic type of dysentery admitted to the Carmichael Hospital for Tropical Diseases showed neither the Flexner nor Shiga type of bacilli, but *Bacterium pseudo-carolinus* has been isolated in the stools. To Lieut.-Colonel H. W. Acton, I.M.S., belongs the credit of first observing that the infection with this bacillus produced certain symptoms and that these improved by treatment with autogenous vaccines.

During the summer of 1933 a large number of patients admitted under the senior author in the Carmichael Hospital showed the presence of this bacillus in stools on culture. As our knowledge regarding its pathogenicity is still vague, and as doubts exist as to whether it is actually responsible for producing any definite train of symptoms, it was considered advisable to study carefully a series of cases in order to see if any definite symptoms were really produced in patients when this organism is present in the stools. Agglutination reactions of the blood in a selected number of cases and the effects of treatment of the infection with vaccines and bacteriophage were studied.

Before describing the results of these observations in a series of cases studied by us, a few words may be said about this bacillus which is not very well known to the profession in this country.

Bacterium pseudo-carolinus is a non-lactose-fermenting bacillus occurring in the intestines. It is a non-sporing aerobe and has been referred to by Castellani along with various other similar organisms without any special reference to its position in the standard classification and pathogenicity. From some preliminary work done at the School (Pasricha, 1931) there is evidence to suggest that this organism is a phage-modified variant form of the Flexner type of dysentery bacilli. These bacilli occur

in the form of short slender rods with rounded ends. They are non-motile and are Gram-negative in their staining reaction. When cultured on agar medium, there is a fairly rapid translucent growth. In broth there is uniform turbidity. In blood hæmolysis is not produced. On potato medium they grow well, the colonies having a yellowish tint very much like honey. On MacConkey's medium, from the primary growth, giant colonies are formed after 72 hours with leaf-like structures in the spreading margin which are thin and translucent with shallow radial striations. They have the following fermenting properties:

Lactose	..	0
Glucose	..	acid and gas.
Maltose	..	acid and gas

Strains of *Bact. pseudo-carolinus*, isolated from patients where the predominant symptom is stasis, ferment salicin with the formation of acid and gas.

During the months of March to September 1933, *Bact. pseudo-carolinus* was isolated from the stools of 40 patients admitted into the Carmichael Hospital for Tropical Diseases. Out of this number, 28 were definitely admitted with symptoms pertaining to the gastro-intestinal tract. Of these nine showed the signs and symptoms of subacute dysentery of the bacillary type, eleven suffered from diarrhoea only, two had constipation alternating with diarrhoea and six had pain in the abdomen. Another group of four patients were admitted with skin conditions pointing to intestinal allergic manifestations, viz, one had psoriasis, two had pityriasis rubra and one had urticaria. The remaining eight patients were admitted for other causes, i.e., three had fever, one had diabetes, one chyluria, one myocarditis, one anarsarca and one infection with *Tinea violacium*. The last two groups of 12 patients, although they were originally admitted into the hospital for other causes, also suffered from definite symptoms pointing to gastro-intestinal disturbance.

It will be seen, therefore, that in this series of patients all showed clinical signs and symptoms pointing to a definite affection of the bowels. In the large majority (28 cases), the symptoms were of acute or subacute in nature and the patients actually sought relief for gut conditions, while in the smaller group of 12 patients the symptoms had become chronic and were masked by other severer affections, but they undoubtedly existed.

The signs and symptoms elicited in these patients were as follows:—

Signs and symptoms.—Most of the patients with this infection complained of flatulence and vague abdominal pains. Some had tenderness in the epigastrium, others showed symptoms of

typical bacillary dysentery of a subacute type, while still others suffered from chronic intestinal stasis with symptoms of constipation alternating with diarrhoea. Some of them continually passed mucus in the stools and came to hospital for this complaint; others had intervals in which no mucus was passed, but every now and then they suffered from diarrhoea with variable quantities of mucus in the stools. Many of the patients complained of pain of a varying degree of intensity after food, i.e., from a feeling of discomfort to pains of a colicky nature. Usually the pain lasted for a few hours, but in some patients it continued much longer and rarely it lasted all day. Blood was sometimes present in the stools, but usually not in large quantities. Tenderness all along the cæcum and colon was a constant feature in some cases. Most of the patients suffered from flatulence and distension, with or without acidity, after meals. The appetite was good in some cases, in others it was impaired and the patient lost weight.

In a number of cases a complete series of skiagrams after a barium meal were taken. The picture presented in the majority was that of stasis in the large gut. Although the emptying time of the stomach and the small intestine was often considerably shortened, the meal reaching the cæcum in two or three hours, the large gut generally, and the cæcum and the ascending colon particularly, were sluggish and distended, and the transverse colon had dropped almost into the pelvis. The tone of the intestinal musculature and peristaltic movements of the large intestines were both inhibited and often the meal was not evacuated even after 48 hours.

Associated with the bowel symptoms, there were in certain cases toxic manifestations, or the allergic conditions of asthma, urticaria, etc. The general health of most of the patients was poor, they were pale, anæmic and very run down. It may be mentioned here that some of these patients had hookworm infection also, but this was generally mild and could not account for all the symptoms present. The colon was palpably thickened in six cases and some of these patients had amœbic infection also. Combined infection with *E. histolytica* and bacillary dysentery is very common in this country and according to Acton and Chopra (1929 and 1933) this form is most difficult to treat. In most of the chronic and relapsing type of cases that came to our hospital this is a common feature. In such cases rarely Flexner and Shiga type of bacilli are found along with *E. histolytica*, but combination with *Bact. pseudo-carolinus* is more commonly met with. This has been shown by case records published by Chopra and his associates (1933-34). In such patients it is difficult to say whether the symptoms produced are due to one organism or the other, but there is no doubt in our mind that the presence of this bacillus

along with these protozoa intensifies the symptoms and renders the cure more difficult.

A few of the patients suffered from low fever, the temperature rising daily towards the evening. Heaviness of the head and headache were common features. The patients looked tired, were mentally depressed, had little inclination for mental work or physical exertion. The tongue was often coated and the breath foul smelling. The blood pressure was usually low and the patient suffered from shortness of breath and palpitation.

Macroscopical and microscopical character of the stool.—The number, colour and consistency of the stools passed was very variable in different cases. The stools were either diarrhoeic, or constipated, pasty looking or hard; they had a more or less normal yellow coloration or were clay coloured. There was both blood and mucus in the stools in seven patients only, nine patients had mucus only, while the large majority, i.e., 24 cases, had neither blood nor mucus in the stools while in hospital.

Microscopical examination of the stools revealed associated protozoal and helminthic infections as follows:—

In the stool of nine patients *E. histolytica* was found, in one case a large number of spirochaetes, in six cases hookworm ova, in seven cases *Giardia intestinalis*. In a certain number of these patients there were multiple infections, but in none was a combined infection with *Bact. pseudo-carolinus* and Flexner or Shiga dysentery organisms found.

Bacterial culture of the stools.—*Bact. pseudo-carolinus* was isolated from all the cases. In a large percentage of cases repeated plating of the stools was necessary to obtain a positive result, as shown below:—

- 16 cases were positive in the 1st plating.
- 8 cases were positive in the 2nd plating.
- 6 cases were positive in the 3rd plating.
- 6 cases were positive in the 4th plating.
- 1 case was positive in the 5th plating.
- 1 case was positive in the 9th plating.
- 2 cases were positive in the 10th plating.

The difficulty of detecting this infection in some patients can thus be readily understood.

Serum reactions.—The isolated organisms were tested with the serum of the respective patients in a selected number of this series with the following results:—

The agglutination was positive in 8 cases, 5 giving the reaction in a dilution of 1 in 160, one in 1 in 80 and one in 1 in 10. Entirely negative results were obtained in 21 patients.

Tests with bacteriophage.—The strains isolated were tested with stock dysentery phage in 16 cases, but only in 8 cases were the bacilli lysable *in vitro* by the bacteriophage used. Even after treatment with bacteriophage the infection could not be eradicated in most of these cases and *Bact. pseudo-carolinus* was isolated from the stools. An interesting case

of two types of *Bact. pseudo-carolinus*, one lysable by phage followed by the appearance of a non-lysable type (after treatment with phage), has been recorded. When phage was prepared for the resistant strain and the patient was treated with it, the infection disappeared and the patient improved considerably.

Discussion.—A perusal of what has been said above will show that *Bact. pseudo-carolinus* is met with in the stools of a large number of patients admitted into the Carmichael Hospital for Tropical Diseases suffering from gastrointestinal symptoms. Looking at it purely from the clinical point of view, it is remarkable that infection with this bacillus has been diagnosed with increasing frequency during the years that roughly coincide with the introduction of treatment with bacteriophage. This may mean one of three things. Firstly, it may be a mere coincidence; the second possibility is that attention has only been directed towards this bacillus during these years and that therefore it is being isolated more frequently; the third possibility is that this bacillus may be a phage-modified form of dysentery bacilli particularly of the Flexner type. The third proposition is of very great importance from our point of view, but it is very difficult to come to any definite conclusion with regard to it without careful bacteriological study.

The association of the bacillus with chronic infection with *E. histolytica*, hookworm, etc., has been brought out in our series of cases. It is possible that some of the symptoms described may be produced by the allied conditions and not by this bacillus. A careful study of the signs and symptoms, taken as a whole, in this series, and in a large number of other cases, not so thoroughly studied, leads us to believe that the train of symptoms produced can be definitely assigned to the presence of this organism. The group of symptoms appear to form a definite entity not met with in any of the concomitant infections. In this opinion we are supported by Miss North, the nursing sister-in-charge of the hospital, who is a very acute observer and who has watched hundreds of these patients. Although a clinical study of this nature cannot supply a definite proof of the pathogenicity of this bacillus, our impression is that the presence of this bacillus in the gut does give rise to a train of symptoms which are not met with in other intestinal infections commonly encountered in Calcutta. Whether this bacillus is responsible for the production of these symptoms or whether it is merely a passive associate on account of certain conditions set up in the gut by some factor or factors, it is difficult for us to say.

The agglutination reactions obtained in this series were inconclusive. In 8 cases the agglutination titre of the serum was fairly high (1—80 to 1—160), but in the majority no reaction could be obtained.

Only a complete bacteriological study can throw light on the pathogenicity of this organism and we are glad that Captain C. L. Pasricha, I.M.S., and his associates in the Department of Bacteriology have taken up this study. All that we are in a position to say at present is that there is a good deal of clinical evidence in favour of its being a pathogenic organism.

Treatment.—The line of treatment adopted was that recommended by Lieut.-Colonel H. W. Acton. This has given fairly satisfactory results so far as the amelioration of the general conditions of the patients and the symptoms produced are concerned, but the infection is often not eradicated. The usual medical treatment with saline is given when motions are frequent and contain blood or mucus. Constipation if present is relieved and the bowels are regulated. Any associated protozoal and helminthic conditions are treated. When the acute symptoms subside or in chronic cases a course of vaccine is given, as laid down below, the injections being given twice weekly.

- 1st injection 10 millions.
- 2nd injection 20 millions.
- 3rd injection 30 millions.
- 4th injection 40 millions.
- 5th injection 40 millions.
- 6th injection 40 millions.

In some patients the reaction after an injection is severe, a rise of temperature and colicky diarrhoea being produced. If this is the case the next dose should not be increased. A mild reaction after an injection is desirable, and is beneficial. Throughout the course of injections the patients are kept on calcium lactate, 10 grains, and extract of parathyroid, 1/10th grain, twice daily. After the course of vaccines the patient is put on a general tonic consisting of iron, arsenic and strychnine. In debilitated patients with long-standing infection a change and rest to an agreeable climate is necessary. If the bowel symptoms do not completely subside a month's course of standardized liquid extract of kurchi in doses of one drachm twice daily should be given. The kurchi alkaloids have a sedative effect on the gut and increase the tone of the intestinal musculature.

The question of diet is very important. The carbohydrate in the diet, particularly such articles as rice, potatoes and sugar, should be cut down to a minimum, the diet being mostly protein. Most of the patients improve rapidly under this treatment, but in some of the chronic cases the improvement is temporary and relapses frequently occur.

Summary

1. *Bact. pseudo-carolinus* is a Gram-negative, non-motile, non-lactose-fermenting intestinal organism of the genus *Bacterium*. Further differentiation of the bacillus from other organisms of the same group is determined by

THYROID EXTRACT IN PROSTATIC ENLARGEMENT

By HENRY SMITH, C.I.E.

LIEUTENANT-COLONEL, I.M.S. (retd.)

Blenheim, Main Road, Sidcup

LITTLE is taught in the medical schools, or even in the books dealing with the subject, about the early symptoms of prostatic enlargement until the patient comes near the catheter stage.

Enlarged prostate does not grow in a night, but is of slow growth, the process extending over several years, during which time the case is, or should be, in the charge of the general practitioner, though even he comes on the scene much later than he should do, I suppose, owing to sentimental reasons on the part of the patient.

The earliest symptom is congestion of the penis in the early morning and after a siesta indicating a call to pass water, which when passed relieves the congestion. Later on, this

(Continued from previous column)

its fermenting action on carbohydrates; it produces acid and gas in glucose, and maltose and mannite. Its exact position in the classification of that genus has not been worked out.

2. There is some evidence to suggest that *Bact. pseudo-carolinus* is a phage-mutated variant form of *Bact. flexneri*. Although there is some presumptive evidence in favour of this on the clinical side, the evidence on the bacteriological side is not as yet conclusive.

3. The clinical symptoms associated with this infection have been described in detail. A study of these tends to show that this bacillus is associated with a definite train of symptoms not met with in other intestinal infections. The clinical evidence in favour of this bacillus being pathogenic is strong.

4. The general treatment adopted and the specific treatment with autogenous vaccines has been described.

We are very grateful to Captain C. L. Pasricha, I.M.S., Professor of Bacteriology, and Dr. K. Banerji for their help in this work.

congestion becomes intensified constituting a prostatic erection, with a feeling radiating into the testicles. Passing water at once relieves this. The passage of water through such congestion is in a reduced stream until the erection has subsided, as would be expected. These erections are not associated with any sexual feelings, but are purely of prostatic origin. These symptoms do not indicate the need of emptying a full bladder as in youth, but the patient soon learns their indication. The frequency of micturition varies from twenty times in the night in some developed cases to once in the night in the very early stage.

There gradually develops a reduction in the size of the stream especially at the end of micturition, which as time goes on slows down to end in a dribble—practically out of control of the patient. When he has got thus far he is in, or is close to, the stage when there is some residual urine left in the bladder. The experienced surgeon when examining by the rectum will find varying degrees of enlargement. This examination should always be done. Cancer of the prostate, being one of the three largest groups of that disease, should always be under consideration in such cases. The enlarged non-cancerous prostate has a relatively soft and elastic feel whereas a cancerous one has a characteristic hard feel to the finger, which when once experienced will not easily be forgotten and is as diagnostic as the microscope. When the patient comes to the dribble stage he may on short notice need a catheter, due to a sudden more acute congestion than usual. From this stage the case is well known to every practising member of the profession.

The following case will give us a foundation of facts on which to speculate :—

Case.—A. B., a man about seventy, six feet two inches in height, normally about sixteen stone, had put on weight to over nineteen stone. His blood pressure was 156, indicating an age of fifty-six years, which, both physically and mentally, he looks like. He is organically sound in every other respect apart from the early stage of prostatic enlargement having reached the early dribble stage above noted and also having a trace of residual urine.

My first objective was to get down the weight. I administered rapidly-increasing doses of thyroid extract (Burroughs and Wellcome) until I reached twelve grains daily. Twelve grains gave the usual symptoms of an excessive dose. I fell back to ten grains daily which was tolerated well for six weeks, with every feeling of well-being. At this stage I stopped the thyroid extract for three weeks, at the end of which time he had lost over three stones in weight.

Before administering the 'thyroid' the patient had a tendency to yawn much more than is normal, but almost from the commencement of the administration the yawning ceased.

He could pass water much more freely. The dribble stage had disappeared and at the end of the course the trace of residual urine above mentioned had ceased. The prostate was perhaps somewhat smaller to the feel per rectum, but on the amount I would not be dogmatic. The prostatic congestions and erections of the penis ceased, and sexual capacity was diminished at the same time.

About three weeks after the end of the course of thyroid extract the whole pre-thyroid-extract condition—sexual, urinary and yawning—were being resumed. Four and a half grains of thyroid extract were given daily: on the fifth day there were unmistakable signs that this amount was not well tolerated and it was stopped. The symptoms had at once responded to this dose. The day after ceasing the thyroid extract, the testicles seemed softer and the softening increased for about four days. This softening was associated with shrinkage in size until their cubic capacity was reduced by twenty-five per cent. These facts were unmistakable. From this stage it took between three and four weeks for the original condition to show signs of being resumed.

One grain daily was then given; as this was not enough, it was increased to one and a half grains, and later two grains, which proved quite satisfactory. He has been on two grains for the first two months. This amount, which leaves his sexual power though reduced, presumably represents his thyroid deficiency. His feeling of well-being has increased and at present his weight is stationary though throughout there has been no change in diet or exercise.

Those of us who remember the days before Freyer commenced enucleation of the prostate remember that castration was vaunted as a remedy—but the results were not satisfactory enough to compete with Freyer. This procedure was based on the fact that eunuchs do not develop prostates. While castration before any symptoms of enlarged prostate develop, or even in the early stage of enlarged prostate, might prevent development, it could not be expected to cure it, once enlargement was in the catheter stage such as was the case with those submitted to this procedure. It might, and I think it did, relieve the congestion of the prostate and thus relieve the patient to that extent, but it could not be expected to reduce the hyperplasia existing at the time or if it did it would only be to a trifling extent.

The point which concerns me was the unanimity of opinion at that time that the cause had its origin in the testicles. I do not think that this is challenged to-day. I assume that the internal secretion of the testicles accounts for a number of things, enlargement of the prostate among them, and that the external secretion or semen is merely concerned with reproduction.

Let us now come to the case of the patient A. B. :—The complete wiping out of sexual desire and of the symptoms of enlarging prostate at the same time under the influence of the thyroid extract administered, their resumption a few weeks after cessation of its administration, and repetition of this state of affairs, with the immense reduction in the size and tension of the testicles after a second course of thyroid, demonstrates to my mind that the internal secretion of these organs is the cause of enlarged prostate. The action of thyroid extract leads definitely to the conclusion that the reason why enlarged prostate is not universal, but very far from it in the prostatic period of life, is that patients who develop enlargement are suffering from deficiency of thyroid endocrine; in short, that their thyroid and testicular endocrines are not balanced as

they are in early life, and in those who escape enlargement in later life.

I regard the difference in A. B.'s susceptibility to thyroid extract as indicating that he could carry ten grains daily till his fat was consumed down to the physiological limit after which four and a half grains was too much.

The suddenness and the extent of the improvement in the passage of urine and its prompt completion can only be explained by the complete reduction of congestion of the prostate (as well as of all the sexual organs).

When the patient was seven weeks under treatment I passed a catheter and found no residuary urine. I repeat that the whole of this case proves, as clearly as anything clinical can be proved, that prostatic enlargement is based on chronic congestion of the prostate due to want of balance between the thyroid and testicular endocrines.

Cancer of the prostate.—This is generally admitted to be the condition on about fifteen per cent of the enlarged prostates operated on; my own experience would be nearer twenty per cent. These are usually cases of long standing and are usually of under medium size and hard to the feel through the rectum, a feeling which is diagnostic. Is this cancer based on chronic irritation which is here as in many other cases associated with chronic congestion? We know that such congestion exists in the scrotum in chimney-sweeps' and cotton-spinners' cancer, etc.

Is chronic congestion the foundation on which these cancers are based, prior to the wandering of epithelial cells into mesoblastic tissue?

Let us now speculate as regards cancer of the uterus and breast. Like the prostate in the male these are parts of the sexual organs and in these organs cancer occurs after the menopause, as cancer of the prostate occurs in the corresponding period in the male. Cancer of the cervix uteri is preceded by a period of congestion followed by bleeding when it is called erosion and later on becomes cancerous. Are these cancers ultimately based on chronic congestion?

The uterus is embryologically analogous to the prostate in the male. If we have chronic congestion of the cervix uteri common why not chronic congestion of the lactiferous ducts which I assume is the seat of origin of most cancers of the breast? If so, is such congestion the foundation of these cancers?

It would be interesting in these bleeding cervixes to try treatment with maximum doses of thyroid extract and see if they are due to want of balance of the thyroid and ovarian endocrines, as in the analogous case of the chronic congestion in the patient A. B., and its control. The stakes are large and there is no risk in the experiment, but in experimenting, the maximum dose that the patient can carry must be found and the dose kept near that

ACUTE BACILLARY DYSENTERY IN CHILDREN: ADVANTAGES OF ITS TREATMENT BY PETROLEUM AND ALLIED PREPARATIONS

By T. H. GUNWARDENE, L.R.C.P. (Lond.)
M.R.C.S. (Eng.)

Hospital for Sick Children, Bambalapitiya, Colombo

THE writer has used liquid paraffin in the treatment of bacillary dysentery in children for a number of years, and his experience has led him to the conclusion that, provided the child has not received any preliminary purgation or other unsuitable treatment and that satisfactory nursing is available, he can now give a favourable prognosis in this serious disease of childhood.

Symptomatology.—The condition is most common in children between the ages of two and five years. The first attack of bacillary dysentery as a rule sets in with dramatic suddenness.

The first symptom is usually a rise of temperature, with chilliness or actual rigor and, in younger children, convulsions. For a few hours one is at a loss as to the cause of the temperature, chilliness or convulsions; but very soon, as a rule within six hours from the onset, vomiting, more or less severe, sets in, followed almost immediately by copious and very offensive watery motions most often without any obvious blood. Then the characteristic intermittent griping abdominal pains with nausea and more or less continuous tenesmus sets in. The tongue is, as a rule, covered with a thick fur. The stools are now watery and remain so for the first twenty-four hours or so, but later they become the characteristic, tenacious, blood-stained mucus in varying shades of green and brown due to the unaltered bile. The number of stools in a severe case, without active purgation or with only a mild aperient, is seldom less than one every half hour, if trouble is taken to change the napkin with each motion, as is usually done in private cases. The initial hyperpyrexia, which may be as high as 106°F. and accompanied by drowsiness and headache, soon settles down and for the next two or three days takes on an intermittent character. By the third or fourth day the temperature is normal, and a

(Continued from previous column)

point if the experimenter is to get results. There should be no half measures. Half measures are useless in most things and in none more than in these cases.

In the case of the prostate the doctor in charge *must* get on to the case when the very earliest symptoms appear—if he is to expect maximum results. There is little use in testing this agent on an advanced prostate. The experimenter will get no more from it than was got by castration in the catheter stage.

child usually begins to take a passing interest in a toy or picture book, and one is able to pronounce the patient definitely out of danger.

Below is the temperature chart of a typical acute case in a child $4\frac{1}{2}$ years old.

and the red cells in agglomerated masses and reddish brown in colour. The presence of the macrophage cells is another characteristic feature of the bacillary stool. The mistake liable to occur is the confusing of the large

Prakarama, F., age $4\frac{1}{2}$ years, male child.

The stools are now at longer intervals and the griping pain tolerable. Such in brief is the course of the acute and anxious stage of the illness when treated with any preparation of petroleum.

Diagnosis.—Though the clinical picture is so characteristic, I have had the stools of most of my patients examined microscopically and culturally. The preliminary report has always been 'no amœbæ, cellular exudate of bacillary type present'. *Bacillus dysenteriae* is not always isolated culturally. In thirteen cases of the type described above and in which I have kept careful notes, the Flexner organism has been isolated three times, and the Shiga not at all. This is not difficult to understand, as these bacilli are rapidly outgrown by the normal intestinal flora. To the experienced pathologist however the cytological picture of the cellular exudate of a fresh stool in the early stages is sufficiently characteristic to give a definite diagnosis for practical purposes. The polymorphonuclear leucocytes and pus cells to the extent of nearly 90 per cent intermingled with unaltered red blood corpuscles, as isolated cells or in normal rouleaux formation, present a different picture to that of the amœbic stool, where the pus cells are scanty and degenerated,

Dotted line indicates number of stools.

endothelial macrophages, with their ingested red blood cells and leucocytes, for vegetative forms of *Entamoeba histolytica*. One has also to bear in mind the possibility of a double, bacillary and amœbic infection. Personally, I have never diagnosed this double infection in a child.

Prognosis.—Having had no deaths amongst cases that I have treated from the commencement of the illness, I invariably give a good prognosis. I am extremely guarded, however, when a case comes to me after initial purgation either with castor oil or sulphates or when opiates have been given as indicated by pinpoint pupils. In either case, depending on the degree of dehydration present as a result of the purgation or the degree of drowsiness as a result of the narcotic, I refuse to give a prognosis until 24 or 36 hours have elapsed. In these cases one can hope to overcome dehydration within this time, but the drowsiness, if marked, practically never, even in older children.

Treatment recommended.—I have never been convinced of the need for inducing active purgation in the case of a child whose abdominal contents nature is actively attempting to clear, whether we like it or not, in the course of the next twelve to twenty-four hours, by vomiting

at one end and purging at the other. It may be that adults, unlike children, can withstand such treatment, and that dehydration does not set in as rapidly as in children. The vomiting that is present, and the nausea that follows prevents us from making good orally the loss of fluid that is taking place as a result of the continuous diarrhoea, and to purge further such a child is to dehydrate him to such dangerous degrees as to necessitate subcutaneous or intraperitoneal salines. There is yet another danger of active purgation that children risk more than adults, and that more in private than in hospital practice. The child unlike the adult may not call out for water to satisfy its thirst, and may thus be deprived of what it needs most. Though a trained nurse may be impressed with the necessity for water, not so an unintelligent parent or relative, and it is particularly under such circumstances that active purgation produces the most fatal results.

The suggestion for treating acute bacillary dysentery in children without active purgation but with the use of a lubricant, such as petroleum, is based on scientific principles and practical experience. I am inclined to believe that the view, widely prevalent amongst the public and some medical men, that ayurvedic treatment is better in dysentery than western methods, is in great part due to the active purgation resorted to by us, and to some extent to the injections so freely administered as a routine, without taking into consideration the type of dysentery present.

The form of petroleum I most commonly use is Nujol in the case of smaller children, and Hydrolax in older children. The choice is made because Nujol, being less viscid, is more easily made into a palatable emulsion with a small quantity of water. My usual prescription, for a child two years of age, is :—

R			
Sodii bicarbonatis	grs. 5
Nujol	drachm $\frac{1}{2}$
Tincturæ cardamoni compositæ	min. 10
Syrupi zingiberis	min. 10
Mucil. tragacanthæ	q. s.
Aquam anæthi	ad drachm ii.

Even larger doses can be given with safety and great advantage. This I give every two hours when the child is awake, for the first twenty-four to thirty-six hours, and when the motions become less frequent, the tenesmus less severe, and the child free of fever and tolerably happy, I give larger doses at longer intervals. Paraffin is continued to the very end of the illness, and when the motions become still fewer I wash out the bowel once or twice a day. The washing out of a bowel that is so thoroughly lubricated is a simple procedure and often so free of discomfort that children not infrequently fall asleep during the process. I have gradually abandoned the washing out of the bowel in the early stages, but take great care to wash out later if there is any tenesmus and the stools

are less than three in number. The most important stage at which to wash out the bowel is about the seventh day when the stools are beginning to take on an offensive odour due to the putrefaction of the sloughs. Such a course would also prevent the secondary rise of temperature that sometimes occurs due to retarded elimination. That paraffin acts mainly as a lubricant and not as a purgative is definitely seen by the stools becoming gradually less by about the fourth day, in spite of the continued administration of paraffin.

Intestinal antiseptics I never or seldom use, unless one looks upon petrolcum itself as an antiseptic. I am not prepared to support the statement that petroleum is a 'powerful antiseptic', still one cannot blind oneself to the fact that it does in some degree limit and retard the decomposition of intestinal contents. We know from experience that the stools of persons who regularly take paraffin are, if not actually odourless, at any rate less offensive than when oil is not taken. This may partly be due to the rapidity of transit of the food, but I feel convinced that it acts as an antiseptic to some extent by coating either the bacteria or the nutrient on which they thrive, with an impenetrable film of an indifferent oily substance which is thus prevented from mixing with or becoming incorporated in the protoplasmic contents of the living or the dead cells.

Anti-serum treatment.—Byam and Archibald (1922) state that anti-serum is of *no value* in the Flexner infections as the toxin of the Flexner bacillus is an intracellular one. Serum is of use in Shiga infections only. Acton and Knowles (1928) state that 'infection with the Flexner bacillus is eighteen times as common as infection with Shiga'. On inquiry at the Colombo Municipal Laboratory I am informed that they have not isolated the Shiga bacillus more than four times in the last ten years. Still, if one must administer serum it behoves one to keep in mind that 'serum sent out to the tropics in cold storage rapidly loses its potency in transit and storage'. How much more so must it be in Ceylon where up to very recent times only one firm of chemists possessed an ice chest for storage purposes. Partly for these reasons and mostly because patients receiving my mode of treatment progress so favourably and appear to be free from any severe toxæmia, I refrain from causing even that amount of pain which a serum injection gives rise to, in an already suffering child.

Tenesmus and abdominal pain.—This I am always successful in relieving considerably by attending to the wash out of the bowel myself, and by thorough application of warmth to the abdomen. It is on very rare occasions that I resort to opiates, and then I use tinctura camphoris compositæ administered apart from other medicines, so many drops so many times a day.

CILIA IN THE ANTERIOR CHAMBER AND TRAUMATIC CYST IN THE IRIS

By M. D. ANKLESARIA, D.O.M.S. (Eng.),

F.C.P.S. (Bom.), M.R.C.S. (Eng.), L.R.C.P. (Lond.)

Honorary Ophthalmic Surgeon, Civil Hospital, and
Lecturer in Ophthalmology, B. J. Medical School,
Ahmedabad

TRAUMATIC punctured wounds of the eyeball give rise to a large number of important pathological conditions, both immediate and remote, and among the latter are two very rare and interesting sequelæ which, when they occur, deserve recording, *viz.*, the growth of cilia in the anterior chamber and the development of a cyst in the iris.

M. R. B., a Parsee boy, aged 12, received on the 2nd April, 1927, a severe injury to his right eyeball due to the bursting of a soda-water bottle. A small piece of

(Continued from previous page)

Diet.—Until the child is relieved of all its symptoms and the stage of food craving arrives, which is usually on about the sixth day, I only allow water in abundance, porree* and fried rice cunjee (not arrowroot), weak coffee, weak tea, lemon squash, and sugar candy. To young children who refuse these, lemonade can be given. Before introducing milk I usually allow bread, and later rice and some weak chicken broth.

Summary

1. Considering that it is mucus that nature secretes in abundance in dysentery, it would appear that administering liquid petroleum is the nearest aid to nature.

2. Children so treated from the beginning to the end of the illness show marked improvement sooner than when treated by active purgation. They never get into the extreme restless and anxious state in which dehydrated children are always seen.

3. No intestinal antiseptics are needed, as petroleum acts sufficiently as an antiseptic.

4. Owing to efficient lubrication, intestinal distension practically never occurs; if it does occur, a bowel wash out is easier to administer and the result is more satisfactory than if there has been no lubrication.

5. Flooding the intestinal canal with petroleum appears to relieve adequately the irritation and consequent tenesmus, so that the need for opiates, or other antispasmodics and rectal wash outs, is reduced to a minimum.

glass flew into his eye and caused a punctured wound of the cornea. On examination the eye revealed an oblique penetrating wound of the cornea about three millimetres in size situated at the upper and inner portion of the cornea and about two millimetres

within the periphery. The margins of the wound were a little swollen and slightly gray. The pupil was distorted and a small brownish-black mass was seen between the edges of the wound causing a prolapse of the iris. The anterior chamber contained a small blood clot and was very shallow on account of the escape of the aqueous, and the intra-ocular tension was low. In punctured wounds such as these the fate of the eye depends upon infection—whether primary, introduced at the time of the injury, or secondary in nature, by extension from the conjunctival sac which is seldom sterile. The eye and adnexa were carefully cleaned, the lachrymal sac was examined and found normal. After local anaesthesia, the conjunctival sac was irrigated with 1 in 5,000 perchloride of mercury lotion, and an attempt was made to draw the iris out of the wound, excise it on the stretch and replace it by freeing it from the wound. The wound was cleaned by touching it with the twisted end of a tiny cotton swab dipped in tincture of iodine, atropine was instilled, and the eye was bandaged. On the next day there was some severe injection, both conjunctival and ciliary in nature, the iris appeared inflamed and muddy-looking, and the pupil had only slightly responded to atropine below and to the outer side of the wound. Some exudation was also noticed in the anterior chamber and the lens had become hazy owing to the injury having involved its capsule also. Atropine was continued, blue ointment prescribed for rubbing on the temple, and potassium iodide and mercury to be taken internally. The lens gradually became opaque and cataractous due to the permeation of the aqueous inside the capsule. In course of time the injection grew less and less, the exudation disappeared, the wound healed up, and the anterior chamber was re-established, but it was unequal in depth as the upper and the inner part of the pupil had formed a synechia with the upper lip of the wound and was drawn forwards. The rest of the pupil was fairly dilated and free. The haziness of the lens was now replaced by its complete opacity, the lens matter looked swollen and soft, and undergoing slow and spontaneous absorption due to the permeation of the aqueous inside its capsule. About the 14th May, the eye became sufficiently free from the tenderness and injection, and on the 26th May needling of the remnants of lens matter was performed and the capsule in the pupillary area was divided and it gaped open fairly well. Four weeks later the pupil was nice and black, and with the scar of the corneal opacity and the distorted pupil his vision came down to 6/36; later on this improved to 6/12 with (+10 d. sphere +2 d. cyl. 20 down in)

glasses, in about six weeks' time.

Nothing was seen of him for about twelve months when he again came up with the history that every

now and then the eye got red, and after two or three days the redness disappeared.

On examination the injured eye revealed a trace of ciliary injection and appeared irritable to examination. The scar of the cornea appeared as having two wings and a centre. There was an anterior synechia underneath the inner wing, and the upper and the inner part of the pupillary margin was adhering to the centre of the scar. Beneath the outer wing of the scar, and taking their origin from it, there were four cilia lying in the anterior chamber. Two were lying stretched on the iris and the other two seemed to have a common origin and to be closely applied to each other near the roots, and to diverge towards the ends. The longer one ran obliquely over a small cyst situated in the iris right up to the periphery of the cornea. The surface of the hairs did not appear smooth and the pigment on them was worn out near the roots and that made them look bleached and grayish. The cyst in the iris was situated in its upper and outer quadrant, appeared hard, and was quite separate from the hair roots. The front aspect of the cyst presented a very thin atrophic web-like wall of iridic tissue underneath which was the grayish shining wall of the cyst. The cyst bulged forwards anteriorly but had not yet touched the cornea nor reached its periphery. The situation was carefully explained to the boy's parents and they were advised to have the cyst and cilia removed to prevent the contingency of future developments arising in the eye, but they remained adamant and desired to leave the eye alone.

30th May, 1933.—Patient sought admission into the hospital nearly six years after the first injury. The history of the case was that there was gradual diminution of vision of the right eye during the last two years without any pain or trouble and that for the past six months the eye was blind and painless. For the last week he had had troublesome vomiting and severe headache accompanied by violent pain in the eyeball and around the orbit.

On examination the eye revealed all the signs of secondary glaucoma. The eye was extremely injected, the cornea hazy and the anterior chamber of unequal depth—being very shallow in the upper half. Four hairs were noticed in the upper part of the anterior chamber. The bulging cyst in the iris tissue had rendered the latter very thin like a cobweb, and both the cilia and the cyst were nearly in contact with the posterior surface of the cornea. The pupil was dilated and fixed and the tension was raised to 50 millimetres measured with Schiötz's tonometer. There was neither projection nor perception of light. It was decided to remove the hairs and the cyst and to relieve the pain without sacrificing the eyeball.

Under local anaesthesia an incision was made in the upper part of the cornea and a long bridge of conjunctiva was kept. From under the bridge all the four hairs were removed from the anterior chamber. The cyst was gently grasped with iris forceps and removed from the thinned cobweb-like iridic tissue and an iridectomy was also done. Recovery after operation was uneventful and the eye soon became quiet and free from pain. Subsequently, it was found that there was a detachment of the retina, which was the cause of the failure of the vision, and that the secondary glaucoma was a superadded temporary condition which was relieved by the operation.

The development of cilia in the anterior chamber and of the cyst in the iris are equally rare and interesting. The causal relationship which exists between traumatism and tumour in general surgery holds good, though to a lesser degree, in the case of the eye and manifests itself in the development of these conditions. Traumatic cysts of the iris are, for the purpose of description, best divided into iris cyst proper

and iris-chamber cyst, i.e., those situated partly in the iris and partly in the anterior chamber. It is with the former class of case that we are concerned in the present instance. In cases of punctured wound of the cornea, pieces of surface epithelium get detached, are dragged in and become implanted on the iris, and, getting well nourished there, proliferate and form cysts. They may occur either as small solid pearl-like tumours, composed of concentric layers of flattened cells, or on the other hand the central cells may undergo cystic degeneration and form an epithelium-lined tumour known as an implantation cyst. The latter being the commoner of the two, it occurs as a grayish looking small flat cystic tumour situated in the iris; the wall formed by iridic tissue is clearly seen with the magnifying lens, the contents being sometimes clear, sometimes turbid fluid. More often these cysts continue to grow and then symptoms of irritation of the eye, iritis, iridocyclitis and a rise in the intra-ocular tension occur. The growth may take place forwards and when it comes in contact with the posterior surface of the cornea, the latter becomes opaque. When it grows backwards the lens may be tilted and pressed upon, and may become opaque, and when it becomes enlarged secondary glaucoma may arise. The first variety, viz, the pearl cyst is much rarer than the other, and in this case the tumour appears not so soft and cystic, but fairly firm and pultaceous, and gives the shining lustre of mother-of-pearl from which it derives its name. The pathogenesis of these varieties of cysts has been variously interpreted. The epithelium from the cornea or the conjunctiva gets dislodged by the injury causing a perforating wound and is carried into the tissue of the iris which is of mesoblastic origin and devoid of glands or epithelium and it subsequently proliferates and forms the cyst. Another theory, known as the extension theory of Stölting (Fuchs, 1923), is that during the process of healing the cells of the surface epithelium, not content with growing anteriorly, may grow and migrate into the wound, then spread over and into the tissue of the iris exposed in the area, and there proliferate and form a cyst for which they have an inherent tendency. De Wecker states that these cysts are due to sacs formed by folds of iris tissue and filled with aqueous, by the iris tissue being split by laceration or hæmorrhage, or by small foreign bodies getting lodged in the iris and, on account of the inflammation set up there, becoming lined with epithelium. With regard to the pearl cysts, which are sometimes associated with cilia in the anterior chamber, the explanation is that the epithelial cells of the hair bulbs of the eye lashes get torn, are carried by the penetrating blow into the anterior chamber, get transplanted in the iris, proliferate there, and form the cyst.

ANTI-TOXIC IMMUNITY TO DIPHTHERIA AMONG A GROUP OF INDIANS IN NAINITAL DISTRICT, U. P., INDIA, AS EVIDENCED BY THE SCHICK TESTS

By A. N. DAS, M.B., B.S., D.P.H., DR.P.H.,

Medical Officer of Health, Benares City, India

(Late Chief Medical Officer, Tarai and Bhabar Government Estates, Nainital)

DIPHTHERIA as an epidemic disease is comparatively infrequent in tropical countries. There is evidence, however, that the disease is endemic in India and in other equatorial zones.

From studies made in a number of countries, the epidemiology of the disease has become more easily understood than before. Certain features may, therefore, be now fitted into the epidemiological conception of this and other similar diseases. For example, it is known that diphtheria is more concentrated among children under four years of age in tropical than in temperate countries. Thus Doull (1928) gives the proportions of deaths in the 0-4 years age group to the total at all ages as 45.55 per cent in England and Wales during 1919 to 1920, as 71.99 per cent in Italy during 1915 to 1921, 60.91 per cent in London during 1910 to 1919, 71.58 per cent in New York during 1917 to 1924, 80.95 per cent in Rio de Janeiro during 1908 to 1916 and as 91.79 per cent in Manila during 1917 to 1924.

(Continued from previous page)

With regard to the origin of the cilia in the anterior chamber the most plausible explanation is that they must have been driven inside the anterior chamber at the time of the injury. This view is hard to accept in this case as the eye was carefully examined several times, before, at the time of and after the operation. There is no recollection, however, that the lid margins were specially examined for the purpose of ascertaining whether any cilia were torn away from them or not, on the first day of the injury.

O. L. Sharpe (1925) in a review of this subject states that 75 such cases have been reported within the last 100 years. The period of time these cilia remained inside varies immensely, from some months to 33 years; in my case it was about 5 years. For some time the cilia cause no trouble or symptoms, but eventually symptoms of irritation and later on of inflammation in the eye arise—such as the feeling of a foreign body, ciliary injection, photophobia, lachrymation and pain. Purulent inflammation of the globe may also occur, but it is rare.

Results of the Schick tests done in some tropical countries, in Manila by Gomez, Navarro and Kapauan (1922), in the Federated Malay States by Fletcher (1927), in Rio de Janeiro by Doull, Ferreira and Parreiras (1927) and in India by Rambo (1929), indicate that, at corresponding age periods, anti-toxic immunity to diphtheria is more common among the residents of these places than among those of England or the United States. Significantly enough, however, carriers of virulent diphtheria bacilli have been found to be quite as common by Vardon in India (1923) and by Gomez and Navarro in Manila (1923) as in the temperate climates.

Age distribution of diphtheria cases has been known to vary also with the aggregation of population: it is concentrated in the younger age groups more in the cities than in the rural areas.

The statistics, therefore, show that diphtheria as an infection is quite as prevalent in the tropical or sub-tropical countries as in the temperate, but that as a disease it is less prevalent and is more concentrated in early childhood. This would indicate that host-parasite relationship is more advanced, approaching closer to commensalism, in the tropical than in the temperate zones, the ratio of clinical diphtheria to immunizing infections being lower in the former than in the latter. In other words, sub-clinical infections are more common in the tropics than in the colder climates.

With a view to finding out the status of anti-toxic immunity against diphtheria in an unselected group of Indian children in Nainital district which lies on the foot-hills of the Himalayas in latitude 28° to 29°N. it was decided to perform the Schick tests.

Diphtheria toxin was imported for the writer by Messrs. Mulford and Co. from the U. S. A. For control tests the heated toxin was also imported by them. The tests were read both at the end of 24 hours and 4 days. The pseudo-reactions were classed as negative, unless accompanied by positive reactions as well. The following table gives the results of the tests done in the months of March and May 1933:

Age group (in years)	Total tested	Per cent positive	REMARKS
0-4	17	47.1	Four cases in which results were not known have not been included.
5-9	150	12.7	
10-14	81	4.9	
15-19	13	0.0	
20 and over	23	4.3	
TOTAL ..	284	11.2	

This table shows that susceptibility to diphtheria rapidly decreases with advance of age.

Clinical cases of diphtheria in these parts of the country are almost unknown among Indians; the writer saw only one case of diphtheria during the five years of his stay in Nainital district. It is not, of course, suggested that this was the only case that occurred from the disease during that period. It does appear, however, that the probable explanation of the phenomenon is that sub-clinical infections of the disease are quite common.

Frost (1928) while discussing the epidemiology of diphtheria stated that ratios of infection to immunity and of infection to disease vary widely, in the same population, with age, race, circumstances of known exposure, and, in different populations, with difference in latitude. Certain unpublished studies made by the writer on acute poliomyelitis, a disease epidemiologically very similar to diphtheria, seemed to suggest that these ratios may vary in the course of the same epidemic. Statistics are available on the results of Schick tests done in India on Indians by Rambo (1929) and on Europeans and Anglo-Indians by Fox, McDonald and McCombie Young (1923). These are given below :

RAMBO'S STATISTICS		FOX'S <i>et al.</i> STATISTICS	
Age group	Per cent positive	Age group	Per cent positive
Under 3 years	72.2	1-5 years	54.5
3-6	10.7	5-10 "	51.5
7-10	14.0	10-15 "	41.6
11-14	2.6	Over 20 "	66.6

These statistics indicate that, age for age, the Anglo-Indians and Europeans have a higher susceptibility to diphtheria than Indians. The results are similar to those obtained in the U. S. A. where the white population have at corresponding ages a greater susceptibility than the coloured.

There were only four pseudo-reactions noticed by the writer among Schick tests made. Rambo had 2 such among 197 cases, whereas Fox *et al.* had 12 pseudo-reactions among 271 tests done on Anglo-Indians and Europeans. These reactions have been ascribed to local anaphylactic response to the protein of auto-lysed diphtheria bacilli in the broth. The statistics at our disposal are inadequate, but if the figures indicate a general law regarding racial variation, some explanation will have to be sought for the phenomenon. The question will then be: How do the Europeans and Anglo-Indians get sensitized to the diphtheritic protein to a greater degree than do the Indians?

Summary

1. There are reasons to believe that diphtheria is endemic in India.

2. The morbidity from diphtheria is, for some obscure reason, not high among Indians.

3. The susceptibility to diphtheria rapidly decreases with advance of age in this country, in spite of the fact that as a disease it is not so prevalent. This suggests that infections incapable of producing clinical manifestation of disease are common.

4. More extensive Schick-testing among various races in India are required to elucidate certain important phenomena of the disease.

A Mirror of Hospital Practice

TOXIC EFFECTS OF EMETINE ON THE CARDIOVASCULAR SYSTEM

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)
LIEUTENANT-COLONEL, I.M.S.

and

B. SEN, B.Sc., M.B.

(Carmichael Hospital for Tropical Diseases, School of Tropical Medicine, Calcutta)

S. D., a European female, 48 years old, was admitted into the Carmichael Hospital for Tropical Diseases, under the senior author on 23rd January, 1934, with irritation of the skin all over the body and a general feeling of weakness, depression and debility. The patient suffered from malaria five years ago and was treated with quinine. A year later she had an attack of acute amoebic dysentery and was treated at the School of Tropical Medicine, London, where a large number of *Entamoeba histolytica* were found in her

stools. The treatment consisted of a course of emetine-bismuth-iodide by the mouth lasting for 12 to 14 days, the drug being taken every night in gelatine capsules. The first two doses were vomited, and after six doses of the drug, the patient's pulse became rapid, she felt extremely weak and was consequently kept strictly confined to bed for a week. The symptoms of dysentery disappeared, but the rapid pulse and general weakness persisted, at the time of her discharge from the hospital. She regained her normal health in about a month. The patient returned to India and during the hot weather of 1933 had another attack of malarial fever and was treated with quinine. Soon after this she started passing blood and mucus with her stools, and on examination these showed *E. histolytica*. She was put on emetine, one injection daily for the first six days and after that one every alternate day till a total of nine injections had been given. After the ninth injection, although the symptoms of dysentery disappeared and examination of the stools showed no *E. histolytica*, the patient's pulse became very rapid, she felt very weak physically, was mentally depressed, and had an itching sensation on the skin all over the body which was very uncomfortable. The patient was kept in bed and put on a mixture containing digitalis which she took for about three weeks. The rapid pulse and the general depression however persisted, she could not undertake any physical exertion, and she lost weight. She came to the Carmichael Hospital for Tropical Diseases for investigation and treatment.

The patient on admission was thin, anæmic and debilitated, and complained of a feeling of exhaustion. Physical examination revealed a rapid pulse (90 to 100 p.m.) of low tension, the heart sounds were weak and flabby, and the blood pressure was 106 m.m. systolic and 70 m.m. diastolic. The urine showed no albumin or any other abnormal constituents. There was a good deal of itching of the skin, but no patches of urticaria were visible. Repeated examinations of her stool showed neither protozoa nor any non-lactose-fermenting bacteria. No helminthic ova were found and no malarial parasites could be detected in the peripheral blood; culture for the plasmodium was also negative. Electrocardiographic examination was made soon after admission with the following results:—

P-R interval—0.10 secs.

P-T interval (systole)—0.35 secs.

T-P interval (diastole)—0.24 secs.

Heart rate—104 per minute, regular.

Potential of R wave—1.2 multivolts.

Inversion of T wave in second lead with T-P interval (diastole) less than P-T interval (systole) indicates myocardial damage with tachycardia of sinus origin.

The interesting points about this case are the toxic effects produced by emetine on two occasions when the drug was administered for intestinal amœbiasis. On both occasions the main effects were on the cardiovascular system. The author and his co-workers (1924) showed that marked histological changes of a degenerative character occur in the heart of rabbits after injections of emetine. In this patient the indications of myocardial changes were clearly demonstrated by electrocardiographic tracings. Emetine also has a damaging action on the capillaries, and the senior author has seen several cases in which itching of the skin and even urticaria and large pruriginous plaques were produced and persisted for a month, after a course of emetine. The patient improved with cardiac tonics (iron, arsenic and strychnine), and an electrocardiogram taken three weeks later showed a distinct improvement.

A CASE OF CEREBRO-SPINAL FEVER SUCCESSFULLY TREATED BY INTRAVENOUS INJECTIONS OF UROTROPINE

By B. L. CHOPRA, L.R.C.P., L.R.C.S., L.M., D.P.H.
D.T.M. (Liverpool)

District Medical Officer, North Western Railway
Delhi

A MAN, 35 years of age, was admitted into this hospital about the first week of December 1933 with a temperature of 103°F. He was examined and found to have Kernig's sign and all other clinical signs of cerebro-spinal fever.

A lumbar puncture was done and about 30 c.cm. of turbid fluid, flowing at slightly increased pressure, were drawn off. This was examined bacteriologically and showed meningococci in abundance. Next day another lumbar puncture was done, 30 c.cm. of fluid drawn off and 20 c.cm. of anti-meningococcal serum injected intrathecally. Next day another lumbar puncture was done, and the same amount of fluid was drawn off, and 20 c.cm. of anti-meningococcal serum was injected. As the serum was not having much effect on the temperature and general condition of the patient, daily intravenous injections of urotropine (5 c.cm. of 40 per cent solution) were given. The first injection brought the temperature down and it remained normal throughout the remaining period of his stay in hospital, except on one or two occasions when it was about 99°F.

Twelve intravenous injections of hexamine were given in all. Each injection seemed to improve his condition. Whenever he complained of headache and uneasy feeling a lumbar puncture was made and about 30 c.cm. of fluid removed each time. Five such punctures were made.

On the 31st December (25th day of disease) the patient complained of pain in his joints and looked slightly toxæmic with a temperature of 98.8°F. An intravenous saline (half a pint) was administered and after that day he made an uneventful recovery and

was discharged cured on the 18th January when the cerebro-spinal fluid was found to contain no meningococci.

My thanks are due to the Chief Medical and Health Officer, North Western Railway, Lahore, for permission to publish this article.

VOLVULUS IN A NEWBORN CHILD*

By M. A. H. SIDDIQI, M.S., F.R.C.S. (Eng.)
Professor, Anatomy Department, King George's Medical College, Lucknow

A CHILD, apparently normal, exhibited restlessness and appeared to be in pain on the third day after birth, and on the following day it died. As there was no obvious cause for death a post-mortem examination was performed.

When the abdomen was opened an extremely distended loop of small intestine, deep green in colour, presented in the opening. There was no effusion of fluid in the peritoneal cavity and all the other organs appeared normal.

The distended loop of bowel filled the iliac and lumbar regions on the right side and it was found to be a portion of the ileum about eight centimetres from the ileo-cæcal junction which had been strangulated by an anti-clockwise twist of ninety degrees on a mesenteric axis four and a half centimetres in length.

This case is of interest because volvulus in such a young child is very uncommon, and the direction of the twist was in the opposite direction to that usually seen. The absence of peritonitis is probably explained by the early death of the child and the relatively sterile condition of the intestinal contents at this early age.

A CASE OF STRANGULATED HERNIA RELIEVED BY ATROPINE

By A. R. LODHI, M.B.S., B.M.S.
Medical Officer In-charge, Pandit Dispensary, Sirsi

A MALE patient, R. V. M., aged 57 years, was admitted with a strangulated hernia on the 11th January, 1934.

His temperature was 97°F., pulse 100 p.m., weak and of low tension. He had vomiting, colicky pains and cold perspiration. The inguino-scrotal swelling, which had lasted for six hours, was spheroidal in shape, size about 6 inches by 5 inches, had no impulse on coughing and was tense, tympanitic and irreducible.

An enema, and cold and evaporating lotions were tried before arrival at the dispensary without any good result.

Atropine 1/50 grain was injected hypodermically and was repeated after half an hour, as the first injection had no effect. After one hour and a quarter, the swelling became soft and was reduced gradually by taxis.

A truss was put on as the patient refused to undergo an operation for radical cure.

REMOVAL OF A FOREIGN BODY FROM THE ŒSOPHAGUS

By JAGDISH LAL KAPOOR, B.Sc., M.B.S.
Chief Medical Officer, Faridkot State

A boy aged about 7 years was brought to the hospital by his father with the history that he had swallowed a piece a week ago. The boy did not complain of any pain, nor was there any difficulty in breathing or swallowing.

The father was certain that the piece had not been passed out. The child was having a slight rise of temperature, he had anorexia and there was a slight tinge of jaundice in the eyes.

On screening, the coin was seen at the root of the neck, just above the sternal end of the right clavicle, a little to the right of the mid-line with the flat surface antero-posteriorly.

Under general anaesthesia, with a little manipulation, the piece was removed with a coin catcher.

It is remarkable that the coin could remain in the œsophagus for seven days without any symptoms, the child taking his ordinary food daily during the week.

My thanks are due to Dr. Sucha Singh, Radiologist, Harendra Hospital, Faridkot, for his assistance in the case.

AOLAN *Beiersdorf*

is the classic protein remedy for the non-specific treatment of general and local infections.

is sterile and absolutely non-toxic, produces therefore its full therapeutic effect without unpleasant reactions.

Skin and Venereal Diseases				
Indications	Method	Dose	Interval	Remarks
1. Furunculosis, carbuncles, abscesses, suppurating ulcers, trichophytia (especially deep tr. with infiltrations), pyoderma, tinea, kerion (celsi), folliculitis	Intramuscular	10 c.c.	5-6 days	In trichophytosis and furunculosis, treatment should be continued after improvement; 1-2 injections of 10 c.c. at intervals of 2-3 weeks to prevent recurrence.
2. Eczema, dry and oozing	(a) Intradermal (b) Alternately, intradermal and intramuscular See (2-b)	3-5 c.c. 2 wheals 5-8 c.c. 2 wheals	4-5 days 3-4 days	If the local reaction after intramuscular injection is intense (sometimes observed in extensively affected areas), dosage should be decreased
3. Acne vulgaris	Intramuscular	10 c.c.	5-7 days	
4. Ulcers of the leg				
5 Gonorrhea and its complications: (a) Acute gonorrhea of the posterior urethra.	Alternately, intramuscular and intradermal	10 c.c. 2 wheals	3 days alternating	Clears the urine after a few injections (in acute Gonorrhea of the anterior urethra, Aolan (intramuscularly) will prevent complications.
(b) Chronic gonorrhea in the male without complications.	Alternately intramuscular and intradermal	10 c.c. 2 wheals	3 days alternating	

Dr. O. W., M.D., in G. . . ., writes—

..... I have the pleasure of informing you that your preparation has given these splendid results without causing any sign of inflammation or the slightest pain at the site of the injection even where 10 c.c. have been applied intramuscularly.

THE PHARMACEUTICAL PROFESSION AND THE 'DRUGS SCANDAL'

THE medical profession is not entirely self-contained and independent; certain other subsidiary professions have an important bearing on its successful conduct. One of the principal of these subsidiary professions is pharmacy, because no matter how skilled a medical man be in the diagnosis of his case this comes to naught if the drugs he prescribes are not accurately and honestly dispensed.

The unsatisfactory condition of the profession of pharmacy in India as a whole has been fully established and the facts published in the report of the Drugs Inquiry Committee in 1931, and recommendations for improving, and to some extent standardizing, the educational status of pharmacists throughout India are fully discussed therein, and have since been the subject of editorial comment in these columns, so there is little new to be written regarding this important subject, but we feel that a reminder will not be out of place. It would be most unfortunate if the valuable work of the Drugs Inquiry Committee were to go the way of most committee and commission reports and become forgotten in some inaccessible pigeon-hole.

In another part of this issue we publish the presidential address to the All-Bengal Compounders' Association, delivered recently to them by Lieutenant-Colonel Chopra, C.I.E., I.M.S., who was, it will be remembered, chairman of the Drugs Inquiry Committee, and perusal of this address will show that he at least is doing his best to keep before the pharmaceutical profession and the general public the urgent necessity for raising the former's status throughout the country.

Although it has been demonstrated beyond the possibility of doubt that the education and qualifications of pharmacists and dispensers is deficient in every province in India, the other factor, namely, the impurity and adulteration of drugs, which was the *raison d'être* of the Drugs Inquiry Committee and has recently been attracting the attention of the public press in this country, must be countered by legislation and an improvement in the regulation of the sale of drugs effected at the same time, otherwise simply raising the standard of pharmacists by itself can produce little benefit to the public; it is essential that in these two instances any advances must be made side by side.

The *Statesman* recently devoted a leading article to the subject of impure and adulterated

drugs, and during the past few weeks there have been several reports from Bombay and Madras of public protests on the subject of the 'drugs scandal', as it has not inappropriately been called. These were followed by a letter and a short editorial comment in the *Civil and Military Gazette* of 5th April.

In the present state of the law it is apparently very difficult to take any legal action, even in the face of the most blatant instance of dishonesty.

Only a few days ago a circular, addressed to 'Presidents of Union Boards' but in this instance sent to a medical officer of a group of tea estates, came into our hands. The impression was conveyed that the originators of this circular were a philanthropic society who were prepared for the sake of the 'indigent and helpless victims of malaria' to supply quinine at a reduced price. Quinine compound tablets were offered at less than a rupee per 1,000; if such tablets contained even half a grain of quinine the sale would be conducted at a loss. A philanthropic society which dispenses charity so carelessly that it makes no attempt to enquire into the credentials of the recipients would not exist for long and we may assume that this was not a circular from a philanthropic society, but from a bogus drug-concern whose interest in the 'helpless victims of malaria' amounts to an attempt to persuade union boards to purchase at an 'attractive' price entirely useless drugs, which not only leave the malarial parasite untouched, but discourage the patients from obtaining genuine quinine from other sources, and in a large number of instances thereby actually cause their deaths. The issuers of such circulars are as surely murderers as if they had stuck a knife into the backs of their 'indigent and helpless victims'.

At a later meeting of the All-Bengal Compounders' Association an account of which appeared in the *Statesman* of 28th March, this subject of the adulteration of drugs was fully discussed; at this meeting a new association, named the Bengal Pharmaceutical Association, was formed whose object is 'to establish the pharmaceutical profession on a scientific and ethical basis and to protect the public from the grave dangers to which it is constantly exposed, due to the scandalous way in which the drug trade is carried on in the country'. This statement shows that the new association is alive to the necessity of improving the status of pharmacists and at the same time the quality of drugs. It has begun its life under the chairmanship of Lieutenant-Colonel Chopra, who will be assisted by a strong committee, and, although at present it bears the provincial prefix 'Bengal', we hope soon to see this give place to one of 'All-India', for it is only by embracing the country as a whole that any real progress can be hoped for. Needless

the faeces completely. A glass rod or a small stiff piece of stick may be used for stirring the mixture: if a glass rod is used, it should of course be thoroughly washed before use on a second stool; and if a stick is employed, it is best discarded after being used once.

When the emulsion is satisfactorily made, more salt solution is slowly added, the stirring being continued meanwhile, until the tin is nearly full. At this stage it is an advantage to remove any large flakes of vegetable matter that may have floated to the surface; this can be done without fear of removing any eggs, because they take longer to come to the surface of the fluid. The final filling of the tin is best done with a pipette with a rubber teat, adding salt solution drop by drop until a very slight convex meniscus is formed, and it is easier to judge the correct degree of filling if one stoops so that the eye is nearly on a level with the top of the tin. One of the microscope slides is now carefully laid on the top of the tin so that it occupies a central position, and if the height of the meniscus has been properly judged the surface of the fluid will be in contact with the slide, with the exception of only a small air bubble, and none of the fluid will have run down the outside of the tin. The only way to find out the correct size that the meniscus should be is by personal practice. It is a good thing to place a sheet of glass on the laboratory bench on which to stand the tins, because it provides a good level surface and also is easily cleaned if any fluid happens to run over from them.

The preparations should now be left standing for not less than twenty minutes and not more than half an hour. The reasons for thus limiting the time are that the eggs come to the surface fairly slowly; so, if the slide is removed too soon, it will not have on it the maximum number of eggs it is possible to obtain; and, if the slide is left too long, the salt solution exercises osmotic pressure on the eggs so that the contents become isotonic with the solution and they tend to fall away from the slide.

When the proper time has elapsed the slide is lifted from the tin, turned over and placed under the microscope. It should be lifted steadily and fairly rapidly and at the same time kept horizontal; this is best done by using the thumbs and forefingers of both hands on the corners of the slide. The slide is now quickly turned over without any jerking, so that none of the fluid runs off. It is easier to do this if the slide is turned towards one, that is, if the edge of the slide furthest from the body is turned downwards. A little practice will probably be necessary to find the correct speed at which to turn the slide so that it is not done so slowly as to allow the fluid time to run off, nor so rapidly as to jerk it off into the air.

The slide is now placed under the microscope and examined with a two-thirds objective

and any eyepiece from numbers two to four of any ordinary make of microscope. A cover glass is not needed and the upper surface of the fluid should be focused because the eggs will be floating on it. A mechanical stage on the microscope is an advantage, but not a necessity, and it is not necessary to examine the film of fluid to its extreme edges because as it is convex the eggs tend to float upwards towards the centre of the film.

If this method is properly carried out, it is of such accuracy that if hookworm eggs are not demonstrated after the examination of a patient's stool on two different days, it may be safely concluded that hookworms are not present in sufficient numbers to produce symptoms of disease.

If several stools are to be examined on any given day, it is well to prepare them all first, provided this does not take more than half an hour. They can then be examined one after the other under the microscope and no time is lost in waiting for the first one that was mixed to be ready.

As the microscope slide will be used over and over again, care must be taken that they are properly cleaned, because if they are allowed to become the least bit greasy this will seriously interfere with the results.

Although this method was primarily devised for the rapid detection of hookworm eggs and is still mainly used for this purpose, it demonstrates very nearly all the other helminth eggs found in stools in India, so, for all practical purposes, it may be taken that it reveals the presence of any intestinal helminths found in this country.

Part II

A.—Eggs that are demonstrated by the salt flotation technique described in part I

Hookworm eggs.—Although the eggs of *Ancylostoma duodenale* and *Necator americanus* are stated in textbooks to be of different sizes, those of *A. duodenale* being relatively short and broad compared to those of *N. americanus*, this difference only emerges after large numbers of eggs from both species have been measured and the means of the lengths and breadths are taken, but so many eggs in the two series fall in the intermediate group that measurement of one or two eggs is quite useless as a means of determining the species of the parent worm. A more important reason against wasting time in trying to determine the species of worm in this way is that both worms are got rid of by the same form of treatment and both cause the same symptoms of disease, though there is some evidence that *A. duodenale* is more severe in its effects than *N. americanus* per individual worm. The sizes given in all the textbooks I have consulted for the eggs of these two species are all different, so this indicates that there is considerable variation in the size of the eggs. A convenient

guide in round numbers is to consider the eggs of both these species to be between 0.06–0.07 mm. in length by 0.035–0.04 mm. in breadth, though eggs as much as five microns above or below these dimensions may be found occasionally. *A. braziliense*, the hookworm of the cat, which is common in both dogs and cats in India, may occasionally be found in human beings also, and the eggs of this species are always smaller than those of the other two, being about 0.05 mm. by 0.03 mm.

Hookworm eggs, of whatever species, are symmetrical oval bodies with parallel sides and rounded ends. Under the low power they are seen to have a thin shell with a single contour, and they are practically filled by a segmented morula. It is often stated that the morula is in the four-celled stage of division when the eggs are passed, and this seems to be so generally known that inexperienced workers think that, if they see an egg with more than four cells in it, it must belong to *Strongyloides stercoralis*, but as far as my experience goes with this worm it is practically always the larvæ and only very rarely the eggs that are found in the stools. In a hot climate development of hookworm eggs is fairly rapid so that in a few hours a many-celled morula may be present. From a series of observations I have made in Calcutta I have come to the conclusion that four-celled morulae are rare in hookworm eggs even in fresh stools. On one occasion I found larvæ present within five hours of the stool being passed; this is of course exceptional, but it is quoted to illustrate the speed with which development may take place. It may be taken as a safe rule that if eggs of the correct shape and size are found in a stool they are hookworm eggs, no matter what the stage of development of the contained morula.

Eggs of Ascaris lumbricoides.—*Ascaris* eggs are oval with a thick shell, they are usually surrounded by a thick albuminous coat with a knobby surface something like a mulberry, and stained brown from the faeces. These eggs always contain a single-celled morula and as it takes about ten days for a larva to develop within them they present no difference at the end of a few hours. These eggs measure 0.07–0.05 mm. by 0.05–0.04 mm. In addition to eggs of this type unfertilized eggs, which have quite a different appearance, are often found in stools, but as they are not brought up in salt solution they will be dealt with at the end of the paper along with the other eggs that fail to float by this method.

Eggs of Trichuris trichiura.—These eggs are often described as barrel-shaped, but the ends are very small in proportion to the maximum diameter of the egg. The shell is thick, smooth and is stained dark brown, and there is an opening at each end which is closed by a thick plug-like operculum which is not stained. The development of these eggs is even slower than those of *ascaris* so in fresh stools the contents

are always in the form of a single-celled morula. They measure 0.055–0.050 mm. in length and 0.025–0.020 mm. in diameter.

Eggs of Trichostrongylus.—This infection is fairly common in certain tea districts, particularly in the Bengal Dooars. The eggs are of the same type and general appearance as those of hookworms but they are distinctly larger, the ends are more pointed, and the cell morula occupies only the middle of the egg and does not extend so near to the ends as in hookworm eggs. *Trichostrongylus* eggs of the species found in human beings in India are about 0.095–0.075 mm. in length and 0.045–0.035 mm. in breadth. These eggs are never numerous in the stools and are therefore only rarely seen. The worms themselves are unaffected by treatment, but this is not of great importance as they are never numerous and never appear to give rise to symptoms. But it is important to be able to differentiate these eggs from hookworm eggs, because the writer has had a man with this infection sent to him as an incurable hookworm infection who had undergone five treatments with carbon tetrachloride and was still passing eggs, which were *trichostrongylus* eggs.

Eggs of Enterobius vermicularis.—This worm is more popularly known as *Oxyuris*. These eggs are easily recognized as they are asymmetrical with one side somewhat flattened, and they always contain an embryo in the 'tadpole' stage of development. The shell is colourless. They measure 0.06–0.05 mm. in length, and 0.03–0.02 mm. in breadth.

Eggs of Heterodera radiclecola.—Some years ago an American worker, not skilled in helminthology, reported the eggs of a supposed new human parasite in the stools of army recruits in America, and he called this *Oxyuris incognita* on account of the fancied resemblance of these eggs to those of *oxyuris*. This was followed by the discovery of similar eggs in human stools in various parts of the world including India. Later, a second American found that these eggs were really from a free-living nematode which lived on vegetable matter, and so were accidentally swallowed and appeared in the stools. It is thus clear that they are not true parasites of human beings and are consequently of no real importance. At the same time it is important to know these eggs and to know that their presence requires no treatment. The eggs are large, being about 0.1 mm. in length and 0.045 mm. in breadth, and they are usually slightly flattened or concave on one side. Another characteristic appearance is the presence of large oily-looking refractile droplets at one or both ends of the cell morula. Sometimes these eggs are found containing embryos.

Eggs of Strongyloides stercoralis.—The eggs of this worm are rarely found in stools, as they only appear in cases of acute diarrhoea when the stools are examined immediately. In any case,

keeping the stool for an hour or two will ensure the development and hatching of larvæ, a process which is always much slower in hookworm eggs in stools. The newly-hatched larvæ can be distinguished from hookworm larvæ, but this requires considerable experience in examination of worms, and also much more time than a busy practitioner is likely to have at his disposal. As a practical guide it may be taken that if larvæ are found in a stool on the same day on which it is passed they are strongyloides and not hookworm larvæ.

Eggs of Hymenolepis nana.—It is important to be able to recognize the eggs of this small tapeworm, because it is fairly common in India and it sometimes gives rise to gastro-intestinal symptoms; also the worm itself, on account of its small size, is not seen by the patient like the larger tapeworms are, so its presence may be unsuspected until the eggs are found. It is treated in the same way as *Tænia saginata*, but on account of its power of completing its life cycle in the intestine it is much more difficult to eradicate and so treatment often has to be repeated several times. The eggs are usually brownish in colour and spherical, or sub-spherical, measuring 0.045–0.030 mm. in diameter. The contained oncosphere is much smaller being 0.019–0.016 mm. in diameter, and is surrounded by two membranes separated by an apparently semi-fluid substance. The outer of the envelopes has two nipple-like processes, one situated at each end of the egg, and from these five or six long filaments arise; they are easily seen in freshly-passed eggs. The embryo has three pairs of lancet-shaped hooks, such as are found in all tapeworm eggs.

Eggs of Hymenolepis diminuta.—This worm is a normal and common parasite of the rat, but it is occasionally found in human beings. Although considerably larger than *H. nana* the segments of this worm are rarely seen in the stools on casual inspection, so it is of importance to recognize the eggs. The eggs are oval and 0.085–0.060 mm. in maximum diameter; the outer shell is usually brownish and is somewhat denser than that of *H. nana* eggs. The oncosphere measures about 0.036 mm. in length by 0.018 mm. in breadth, and it is surrounded by two membranes with polar thickenings like those of *H. nana* but without any filaments. The embryo contains the usual three pairs of hooklets.

B.—Eggs that are not floated by saturated salt solution

Fortunately the eggs that this technique fails to deliver by flotation are not of great importance in India, so that few intestinal helminths will be missed if this method alone is used in diagnosis, but it is proposed to give a short description of all the other eggs that have been recorded in patients in India.

Unfertilized eggs of Ascaris lumbricoides.—These are fairly common and may be found

in stools along with fertilized eggs. They are very different in appearance from normal eggs; this can be best appreciated by reference to plate VI, figs. 1 to 7, which shows the commoner shapes that this type of egg may adopt, though much the most usual type is the elongated variety. The contents of unfertilized eggs instead of consisting of a single cell are composed of an indefinite mass throughout which are scattered numerous highly refractile granules. Apart from the recognition of what these unusual eggs are, they are of slight importance because if only unfertilized eggs are present in a stool it means that only female worms are present in the patient, and as the two sexes are fairly evenly distributed it is rare to find more than one or at most two female worms alone, therefore only unfertilized ascaris eggs indicate a light infection.

Eggs of Tænia saginata.—These eggs are slightly oval and they are generally found in the stool without the thick outer envelope, which carries two long filaments. The egg without its outer shell measures 0.04–0.03 mm. in length by 0.03–0.02 mm. in breadth, including the thick brownish shell which has fine radial striations. The embryo within this shell contains three pairs of hooks.

Eggs of Tænia solium.—These eggs are about the same size as those of *T. saginata*, but they are spherical, and this is their only real distinguishing character.

Recognition of the eggs of both these species is of little importance, however, because persons with either of these worm infections practically always come with the complaint that they are passing chains of segments at frequent intervals and these are easily identified.

Tænia saginata is only acquired by eating insufficiently cooked beef, so its incidence in India is confined to those who eat oxen; whereas *T. solium* infection is confined to pork, so this worm is even rarer in India than is *T. saginata*, because the number of people who eat Indian pigs is even less than that of persons who eat beef. A simple method of diagnosis, by the examination of a gravid segment taken from the stools and washed, is to place such a segment between two slides and to apply strong pressure so that it is flattened and thinned sufficiently to become partly transparent. The lateral uterine branches may then be counted with a hand-lens or under the lowest power of the microscope. In *T. solium* the maximum number of uterine branches on one side is twelve, whereas in *T. saginata* there are always more than twenty and frequently over thirty branches on each side.

Bertiella studeri is a tapeworm that has been found in monkeys in several parts of the world, and it has been recorded nine times in human beings. Two of these nine records have been from Eastern Bengal, the last one being made by the writer about three years ago. It is not known how this infection is acquired, but it is

certainly not from eating meat, and it is much more probably picked up from some accidentally swallowed insect which acts as intermediate host.

Eggs.—The eggs of this tapeworm are easily distinguished from those of the *tænia* and *hymenolepis* species that have been described above, for they have a peculiar pair of horns on the outer side of the inner shell which are known as the 'pyriform apparatus', a characteristic of the eggs of all the members of the family *Anoplocephalidae*, to which this worm belongs.

If gravid segments of this worm are found in the faeces, they are easily distinguished from those of the *tænia* because they are always much broader than long, whereas gravid segments of *tænia* are longer than broad.

No trematode eggs float in saturated salt solution, so the only way of finding them is in a faecal smear. Trematode infections in human beings are rare in India, but those that do occur are found mostly in Bengal and Assam, and in all of them there is a close association with the same infections in pigs.

Fasciolopsis buski.—This infection has occasionally been found in Eastern Bengal, though it is much more often found on the eastern side of the Siamese peninsula. Occasionally this worm gives rise to severe intestinal symptoms such as pain, diarrhoea and passage of blood, and in heavy infections ascites and generalized oedema are seen. Death has been known to occur as a direct result of infection by this worm. It is accordingly worth while being acquainted with the eggs of this trematode because such knowledge may be of use in diagnosing an occasional case with otherwise unexplained abdominal symptoms. This is especially important, because correct diagnosis will lead to rapid and certain cure as the worms are almost always totally evacuated after a single dose of carbon tetrachloride or tetrachlorethylene.

F. buski is really a parasite of pigs and only occasionally gains access to human beings, so that it is practically always found in persons having close association with these animals. It is also known that the cercaria (infective stage) of this worm encysts on the outer covering of the water chestnut (*Trapa biocornis*), and that it is swallowed when this covering is being removed by the teeth, a common practice among the people.

Eggs.—The eggs of *F. buski* are oval and rounded at both ends with a thin shell and an operculum at one end. They are usually brownish in colour. They measure 0.14–0.13 mm. in length and 0.085–0.08 mm. in breadth; they are thus practically the same in size and appearance as the eggs of *Fasciola hepatica*, but as far as is known this worm has not been found in human beings in India.

Gastrodiscoides hominis.—This fluke was first described from material obtained from a human

being in Assam, but like *F. buski* it has since then been recognized as a much commoner parasite of the pig than of man. This worm lives in the caecum and colon, and it may possibly give rise to diarrhoea and pain, although the writer has never seen a case of this infection. It is probable that carbon tetrachloride would effect a cure. The life history is not known.

Eggs.—The eggs are oval and have an operculum at one end. They may be distinguished from those of *F. buski* as they are slightly longer and narrower, being 0.15 mm. in length and 0.07–0.06 mm. in breadth.

Paryphostomum sufaratyfex.—Since its discovery this worm has been placed in several different genera but under whatever generic name it may be encountered in the literature, it may be recognized by its uncommon specific title *sufaratyfex*.

This worm was first described from some badly preserved specimens obtained from a girl in Assam and like both the above flukes it is now known to be a true parasite of the pig. This is the only record of its occurrence in a human being and it is possible that it will not live in the human intestine and is only accidentally swallowed as an adult. The writer expresses this view because on one occasion a girl was admitted to the Carmichael Hospital for Tropical Diseases with kala-azar, but without intestinal symptoms, and eggs which were referred to this species were found in her stools the day after admission. Although the stools were all carefully saved thereafter for over a week no eggs were again found, nor were the parasites passed in recognizable form, so it is thought they must have been digested.

Eggs.—The eggs are oval and have an operculum at one end; they are 0.12–0.09 mm. in length by 0.07–0.06 mm. in breadth.

Heterophyes heterophyes.—This fluke is common in Egypt and, as far as the writer is aware, the only instances of its occurrence in India are the one or two unreported cases in which the eggs have been found in the Calcutta School of Tropical Medicine during the course of routine stool examinations.

Eggs.—The eggs have a thick shell with a slight suggestion of a flask-shaped neck at the opercular end, such as is clearly seen in *Clonorchis sinensis* eggs. They are much smaller than any of the above described eggs being 0.3 mm. in length by 0.017 mm. in breadth.

From the above remarks it will be clear that trematode infections play a small part in Indian parasitology as far as human beings are concerned. Of course it is possible that such infections as *Clonorchis sinensis*, or one or other of the Schistosomes, may be encountered in persons who have come to India from endemic foci of these various infections, but they do not occur naturally in this country so, as it has been decided to adhere strictly to the

descriptions of eggs which are actually found in India, no description of them is given.

Part III

The number of drugs recommended for the treatment of all forms of worm infections is enormous, and this in itself is an admission that most of them must be quite ineffective; we have accordingly decided to limit our remarks to those few remedies that we ourselves have found the most effective.

Carbon tetrachloride.—We used this drug for many years, either alone or combined with oil of chenopodium for the treatment of hookworm infection. Although we have seen no fatalities, nor even alarming symptoms from its use, a considerable number of deaths have occurred in labour forces in India, especially in the tea districts. Close inquiry into as many of these cases as we have been able to make has revealed that, although many of them can be attributed to the poisonous effect of carbon tetrachloride when taken either shortly before or after moderate amounts of alcohol, there are still a few remaining deaths that can only be explained on the theory that certain persons possess an idiosyncrasy for this drug, which previous examination will not reveal. These are great objections to any drug, for use on a large scale, especially among coolies who are accustomed to use alcohol in considerable amounts, and our advocacy of carbon tetrachloride has always been qualified by warnings as to the need of care in its use, but we have consistently recommended it because it has appeared to us the best drug available for the removal of hookworms, and we have only recently abandoned it in favour of another chloroform derivative.

Carbon tetrachlorethylene.—We have recently completed a long trial of this drug as a cure for hookworm infection and we have also carefully tested its toxicity on cats, animals which show a marked susceptibility to carbon tetrachloride. Our conclusions are that this drug is possibly a little more effective than carbon tetrachloride in removing hookworms and that it is less toxic; a further great advantage of tetrachlorethylene is that alcohol does not appear to increase its toxicity. It is true that patients exhibit similar symptoms to those noticed immediately after tetrachloride, but the signs are only those seen after any diffusible stimulant and they rapidly pass off leaving no permanent damage.

Oil of chenopodium.—If the dosage is carefully regulated and the persons treated are not unduly debilitated this drug is perfectly safe. It is useful in treating hookworm infection and is also one of the most effective drugs in removing ascaris. Most of our patients have both hookworm and ascaris infections, therefore nearly all our treatments consist of a combination of tetrachlorethylene and oil of chenopodium, the detail of which is given below. In

uncomplicated ascaris infection chenopodium may be given alone or combined with santonin. If given alone this drug is more efficient in divided doses, the total amount administered being more than when a single dose is given.

Santonin.—This drug is approximately as efficient as oil of chenopodium against ascaris, but we find that if the two are combined a slightly higher cure rate is obtained.

Hexylresorcinol.—This drug has been introduced recently for the removal of both hookworm and ascaris, and after testing it in Calcutta we have come to the conclusion that it is not very effective against hookworm, but is fairly good in removing ascaris. It is very expensive and on this account is not suitable for use on a large scale. We have found that it will remove about fifty per cent of tapeworms with one treatment, and as it is relatively harmless to human beings it has a certain value for treating tapeworm infections in persons accustomed to take alcohol regularly, as it is in such people that the use of carbon tetrachloride is always attended by a certain element of danger. As it is not at all unpleasant to take, the fact that the dose may have to be repeated to effect a cure is not of great importance. The efficacy of this drug is greatly impaired by the presence of food in the intestine, so rigid precautions have to be taken if success is to be anticipated. The patient should receive a brisk saline purge the day before treatment and only a very light meal, such as bread and butter and a little milk that evening. One gramme (15 grains) of the drug freshly placed in hard gelatin capsules (four ten-minim capsules are required to contain the dose) are given on an empty stomach the next morning, and no food at all is allowed for at least four hours afterwards. The drug is not absorbed in any quantity so a purgative to clear it out is not essential. Indeed in many cases hexylresorcinol appears to have a distinct but in no way unpleasant purgative action itself, two or three copious watery stools being passed during the five or six hours after its ingestion, but there is no colic or tenesmus attending this action.

Gentian violet.—Ordinary gentian violet for staining or pure crystal violet is used. This is claimed by some workers to be a certain cure for strongyloides infection. We have tried it on a good many patients but have not had many successes, but it may be tried in cases of this infection with gastro-intestinal symptoms apparently referable to the presence of these worms. The way to give the drug is to prepare nine hard gelatin capsules each containing one grain of powdered gentian violet, and to give one capsule three times a day for three consecutive days, and to examine the stools a week later for the presence of worms. No dietetic or purgative precautions are necessary during the course of treatment.

Ancylostoma duodenale and *Necator americanus*.—Take two ounces of a saturated solution of magnesium sulphate and place it in a bottle or flask of three or four ounces capacity; add to this 3 or 4 c.cm. (1 drachm) of tetrachlorethylene and 1 c.cm. (15 minims) of oil of chenopodium; close with a cork and shake violently so as to distribute the drugs in fine droplets evenly throughout the purgative; at once pour the mixture into a glass and give to the patient. This treatment is best given in the morning before breakfast, and no food is allowed until the bowels have acted well; after this has occurred, food may be taken without any restriction. Even if these drugs do not remove all the worms present they stop the female worms laying eggs for about a week or ten days, therefore if the results of treatment are to be estimated by the use of the microscope, the stools should not be examined until about a fortnight later when the treatment can, if necessary, be safely repeated.

Ascaris lumbricoides.—In the treatment of uncomplicated ascaris infection with oil of chenopodium alone it is best to give three doses each of ten minims in gelatin capsules at intervals of one hour and to follow the last dose with a brisk saline purgative after an interval of half an hour. The treatment should be given before breakfast in the morning and no food allowed until the bowels have acted. If santonin is used three grains are given in powder together with 1 c.cm. of oil of chenopodium early in the morning, a saline purgative is given three or four hours afterwards, and food is allowed as soon as the bowels have acted. We have found that santonin given in this way is just as effective as when given at night with a purgative the following morning.

Trichuris trichiura.—This worm lives in the cæcum and it is very difficult to eradicate, but although we do not often completely cure an infection we often note that a large number of these worms are evacuated after an ordinary combined hookworm treatment. Since we have begun the use of tetrachlorethylene we notice more trichuris are being passed than they were with carbon tetrachloride, so it is possible that it is more effective against this species.

Enterobius vermicularis (*Oxyuris*).—The number of drugs recommended for treatment of this infection is an indication that no true cure exists. The main location of these worms is the cæcum so it is not of much use to employ rectal injections such as are often recommended, because all they will do is to remove the worms that have wandered down to the descending colon and sigmoid; all that can be hoped for by this means is temporary relief. It is probable that oxyuris infections frequently die out naturally so if re-infection by the fingers is prevented a case will often clear up. The female worms wander out of the anus at night and deposit their eggs on the skin near by; this

causes intense itching and the desire to scratch. In this way eggs are picked up under the finger nails and conveyed to the mouth, and to prevent this the region of the anus should be smeared with dilute ammoniated mercury ointment every night before going to bed. This serves the double purpose of killing the worms and their eggs and also of allaying the itching to some extent. Children are most easily prevented from scratching the anal region by applying a light splint to each elbow. The drugs used for hookworm treatment often cause large numbers of oxyuris to pass so this may be employed because if such treatment does not cure a case it will at least greatly lessen the number of worms and so hasten the eventual natural cure. Free purgation alone also causes the evacuation of large numbers of oxyuris occasionally, so it is useful to take a brisk saline purge from time to time.

Trichostrongylus species.—This worm has up to now resisted all forms of treatment, but as the infection is not common and is never heavy enough to give rise to symptoms it is not of great importance. Since we have begun the use of tetrachlorethylene we have had one or two patients who harboured this infection along with hookworm, and the trichostrongylus eggs have disappeared at the same time as the hookworms. We have not had enough experience yet to express a definite opinion on this point, but it is possible that this drug is a cure for the condition.

Tænia saginata and *Tænia solium*.—The best drug for removing these worms is carbon tetrachloride; we have found tetrachlorethylene to be quite ineffective for this purpose. No special preparation of the patient is necessary and the only dietary precaution needed is to see that patients have no alcohol for two or three days before treatment. A light meal is given the night before treatment and in the morning 3 c.cm. (45 mins.) of carbon tetrachloride are shaken up in two ounces of a saturated solution of magnesium sulphate. No food is allowed until the bowels have acted, and alcohol is forbidden for two or three days after treatment. We have found this treatment to remove about 80 per cent of tapeworms at the first attempt, but if carbon tetrachloride is contra-indicated the less efficient, but much less toxic, hexylresorcinol may be used. How to use this drug will be found under the description of hexylresorcinol.

Hymenolepis nana.—This worm is removed by the same treatment as will remove the large tæniæ, but it is improbable that a single treatment will suffice to bring about a complete cure. The reason for this is that auto-infection in the gut takes place and the young worms pass through their larval stages inside the intestinal villi. In this position they are not reached by an anthelmintic and although the adults that are in the intestine are cleared

out by the treatment, the young worms develop and in turn come to reside in the gut and thus continue the infection. It is important completely to cure persons if possible because this habit of auto-infection may eventually lead to a very heavy infection from a single adult worm.

Hymenolepis diminuta.—This worm has a complex life history needing an intermediate host and it cannot multiply in the intestine, therefore it is probable that a single treatment, the same as that given for *tænia* infection, will effect a cure.

Bertiella studeri.—This worm is also easily removed by routine tapeworm treatment.

Fasciolopsis buski.—This fluke is easily removed with carbon tetrachloride and probably also by tetrachlorethylene, but we have had no opportunity of trying the latter drug on an infection with this parasite.

Gastrodiscoides hominis and *Paryphostomum sufrartyfex*.—Both these flukes would almost certainly be got rid of with carbon tetrachloride or tetrachlorethylene, but we have never seen a case of either infection in human beings, on which to try these drugs.

Medical News

ALL-BENGAL COMPOUNDERS ASSOCIATION

THE presidential address of Lieutenant-Colonel R. N. Chopra, C.I.E., I.M.S., at the annual meeting of this association, held at the All-India Institute of Hygiene and Public Health, Calcutta, during January of this year, contained matter of such great importance to the medical profession in this country that we have given a very extensive extract from it below:

Pharmacy in India

As a pharmacologist who has to work with drugs, I am very greatly interested in the profession of pharmacy which you practise. The important part which pharmacists play in relation to drugs needs no special emphasis. You, as their representatives in this country, are the custodians of drugs. You prepare and compound drugs and on your efficiency depends the purity and efficacy of the preparations dealt with by you. Your relation to the practice of medicine in everyday life is intimate and you are an integral part of it. The busy physician dealing in diagnosis and treatment of disease has no time at his disposal to dispense his own medicine as he used to do in the old days. Pharmacy has developed enormously along with medicine and the wider scope of the two sciences makes it impossible for the medical practitioner to devote himself systematically to the study of pharmacy. In matters of drugs, their preparation and dispensing, therefore, the physician has to depend entirely on the advice and guidance of the pharmacist. The physician has sometimes to use very potent drugs which require to be handled with most exact and scrupulous care. Skillful dispensing is essential for successful treatment of disease by those practising medicine.

Pharmacy and purity of drugs

Again the question of purity of drugs and the profession of pharmacy are interdependent. In early days pharmacists as a class were practically traders and retail dealers in crude drugs of vegetable and animal origin, and were themselves responsible for their purity and quality. With the development of modern medicine the number of drugs has enormously increased and, by introduction of newer methods of analysis and assay, the realm of pharmacy has considerably widened. The modern pharmacist has to have an intimate knowledge of the chemical and physical properties of drugs and also the necessary knowledge and skill to deal with them. It follows, therefore, that the efficiency of persons, engaged in the exercise of the profession of pharmacy, bears an important relationship to the purity and conformity to proper standards of drugs and chemicals manufactured, imported into and sold in the country. I was, therefore, very glad, when

in 1930 I was appointed chairman of the Drugs Enquiry Committee, to enquire into the extent to which drugs and chemicals of impure quality or defective strength are imported, manufactured and sold in the country, that one of the terms of reference of this committee was 'to enquire into the necessity of legislation to restrict the profession of pharmacy to duly qualified persons and to make recommendations'. It is a matter of common knowledge that drugs in the Indian market are not above reproach and that many of them are of impure quality and defective strength. That in regard to adulteration, deterioration or tampering with the quality or strength of drugs very little distinction could be made between imported and locally-manufactured preparations. Being conscious of the close relationship between the two and knowing the state of the profession of pharmacy in India, I fully realized from the beginning that one could not be improved without the other. The supply of pure and up-to-standard drugs is dependent on an efficient profession of pharmacy. An opportunity was thus offered to me to suggest improvements with regard to this important and yet very neglected profession without which the medical profession cannot efficiently carry on its duties.

Present position of the profession of pharmacy in India

Here I would like to make a brief reference to the present position of the profession of pharmacy in India. It is painful for me to say that there is no organized and self-contained profession of pharmacy in this country in the sense in which it exists in other civilized countries. In this advanced age of systematization and methods in every department of life, this may sound strange, but it is none the less literally true. The profession here is represented by a set of people whose status, functions and duties are ill-defined and improperly understood. They carry on the compounding, dispensing and selling of drugs and chemicals from day to day. They handle drugs and poisons with the utmost ease and freedom and in many cases in ignorance of their properties and potency. They also work as dressers and laboratory assistants in some of the hospitals and dispensaries. Anaesthetists and operation assistants are sometimes drawn from their ranks.

The evidence produced before the Drugs Enquiry Committee regarding the character and quality of work turned out by the profession as a whole in this country was far from being complimentary. All sorts of charges of ignorance, carelessness, and lack of responsibility were profusely levelled against it. The weight of evidence was decidedly against the competency of the profession as practised at present, and the public and medical men all over India expressed dissatisfaction with its work. The reason of this is not far to seek

when it is remembered how intimately connected the profession is with the health and well-being of the people at large. Pharmacutists in western countries are conversant with the science of pharmacy and are even able to carry on the duties of manufacturing and analysing drugs. There is no pretence at the cultivation of the science of pharmacy in this country. The profession carries on the art of dispensing mechanically and the majority of those practising it have neither the general education nor the special training to befit them for the discharge of their responsible duties. It is no wonder that they are not equal to the work. The surprise is how they carry on as well as they do.

Training in pharmacy

The causes of this state of affairs are, firstly, the qualification and training of the profession who carry on the onerous and arduous duties of handling and compounding medicines. No definite and uniform standards of training and qualification is enjoined in different provinces of India. The whole system is in a state of chaos.

In many cases no preliminary qualification is enforced. In others the standard of basic education required is very low. No regular rules regarding the qualification and training of compounders are laid down in many provinces. The training given in most places is of a very elementary nature and unsatisfactory. If one considers the condition of the profession as a whole in this country, one is not surprised at the dissatisfaction held by the public and medical men all over India in respect to it. With the exception of Bengal and Madras, where there are recognized courses, in almost every other province no proper course of instruction is laid down. The standard of education is low and not much can be expected by way of professional training. The state of affairs in this country is widely different from that in other civilized countries, where pharmacists are required to have a thorough knowledge of the science of pharmacy and the manufacture of drugs.

The second reason for this state of affairs is that the legislature in this country has not passed any act dealing with pharmacy. The Indian Poisons Act, and the Indian Opium and the Dangerous Drugs Acts only control the manufacture, sale, possession and import of certain drugs, but have no relation to pharmacy generally. They do not ensure that persons selling or keeping open shops for retailing, dispensing or compounding of poisons and narcotics should possess a competent knowledge of their business.

In a few provinces all chemists' shops are obliged to employ qualified compounders for compounding, dispensing and selling drugs, under the provisions of the Municipal Acts. Rules have been framed by some local governments for the systematic training of the compounders in the medical schools or colleges, or hospitals, as the case may be. In most of the provinces, however, there are no regulations whatever. For the convenience of the government and local hospitals a very poor class of compounders is trained; in others no training worth the name is given. In some cases the licenses issued use the words 'chemist' and 'compounders', but no statutory enactment controls their qualifications. The licenses are granted without regard to the necessity for the employment of a person qualified to handle and sell these drugs. Practically all over the country the dearth of legislation to control the practice of this profession is forcibly brought home.

In those provinces where Municipal Acts are in existence, provisions requiring the registration of shops for the sale of drugs and prohibiting the practice of the profession by unqualified persons are included. There are such acts in Bengal, Bihar and Orissa and Assam. Under the enactment here shops, or places for retail sale of drugs recognized by the British Pharmacopœia, which are not articles of domestic consumption, have to be registered and a license obtained. Only certified

persons under the rules made for that purpose can compound, mix, prepare, dispense or sell drugs in any such shop or place. In actual practice, however, the machinery to see that the provisions of these acts are enforced is very inadequate, and the actual state of affairs is not much better than in provinces where there is no enactment.

Pharmacy a neglected profession

It is quite evident that the advantages accruing from the promotion of pharmaceutical education have not been sufficiently appreciated in India. I have pointed out that the basic education is, in many cases, disproportionately low. With the exception of a few provinces the actual course of training is also generally inadequate. It is grossly insufficient to equip candidates for the proper discharge of the responsibilities which fall on them. The superior career of pharmacists is practically unknown. The profession does not attract pupils of good status and education. The remuneration which they receive bears no proportion to the responsible character of their duties. The result is that the profession commands little or no prestige. If the present needs of the country are to be adequately met, a correct conception of the true character of the profession and of its nature, dignity and functions has to be brought home to the people in general. Public opinion must be so educated as to accord to the profession its proper place in the departments of human activities. It must be made impossible for persons without adequate training and qualification to dabble with the profession. A system of training and education suited to the peculiar conditions of the country should be carefully devised so as to lift the profession out of its present unsatisfactory condition.

The necessity for this overhaul of the profession is accentuated by a consideration of the state of the profession in other parts of the world. Pharmacy has attained a very high standard of development in most progressive countries. It is considered there to be an important branch of applied science. Systematic courses of training are imparted in colleges, which are specially designed for the purpose, known as colleges of pharmacy. The subject forms a part of the curriculum of many universities. The standard of education in some important countries of the west is very high. In Great Britain the candidates for the course of pharmacy have to undergo what is practically a two-years approved systematic course of training for the lower qualification and three years for the higher. University degrees are also open to them if they are matriculants. In the United States of America the minimum course is of three years duration. The minimum degree eligible for registration under most state laws is Graduate of Pharmacy. The degree of Pharmaceutical Chemist (Ph.C.) is given for a somewhat more advanced course and the degree of Bachelor of Science in Pharmacy (B.Sc. in Phar.) is conferred upon many students who take a longer and more difficult course. In almost all the countries on the continent of Europe dispensing is reserved exclusively to qualified people and a very high standard of training is maintained.

The remedy

In view of what has been said it will be observed that pharmacy is still in its infancy in India and the profession has not been organized or classed on any definite basis. I have discussed at some length the present state of the profession of pharmacy as it is practised in India and as it is practised in other civilized countries of the world. Although I have perhaps been too out-spoken regarding the present state of affairs, believe me it is far from my thoughts to hurt your feelings. My object is to bring home to you the real state of affairs so that you will realize how your profession, which like medicine is a noble profession, is being practised in this country. Owing to circumstances over which you have no control, it has not only been relegated to the background but has at times

incurred the odium of the public. The remedy of the evils from which you suffer is obvious. You should thoroughly overhaul the profession as it is practised at present and you should reorganize it on a firm and All-India basis. Without going into detail the main points to which attention should be paid are, firstly, that the basic educational qualifications of the entrants to the profession should be raised; secondly, the professional training should be made more practical, thorough, exacting and comprehensive; thirdly, the standards of education should be made uniform all over India; and, lastly, the question of restricting the profession to qualified persons by laying down qualifications, statutory or otherwise, is of very great importance. The exercise of any profession should be subjected to restrictions which make for efficiency and improve the status, dignity and sphere of usefulness. Legislation will have to be enacted, but, if you put your own house in order and improve professional education, it is bound to follow.

I studied the whole question very carefully and in the *Report of the Drugs Enquiry Committee* you will find a scheme for putting the profession of pharmacy in this country on a solid foundation. This scheme was worked out with due regard to the conditions prevalent in India, and, although the scheme may not be perfect and may have shortcomings, it is the best solution of the difficult problem we could find to cure the crying evil, without violent disturbance of the existing state of affairs. I wish to draw the attention of those who are interested in the uplift of the profession to the scheme propounded in this report. Try and improve on it if possible and if you succeed nothing will give me more pleasure. An association such as yours is one which is eminently fitted for such uplift work, and I am glad that you are in earnest about it. Your suggestion for changing the name from Compounders Association to Pharmacists Association is a move in the right direction and will be a step towards raising your status. You may rest assured that, so far as it lies in my power, I will do my best to guide you into the right path towards laying the foundation of the profession of pharmacy in this country.

I would like here to impress on you gentlemen that the changes necessary for the building up of a profession of pharmacy cannot be effected at once. Time, hard work and patience are needed. It is just possible that in the beginning some of you may feel the contemplated changes to be a hardship. The fruit of these changes will, however, gradually come to you. The process of replacement of the old order by the new must necessarily be gradual so as to prevent those practising the profession at present from suffering. If the main outlines of the scheme suggested in the *Report of the Drugs Enquiry Committee* are given effect to, you will see within a decade the beginning of a profession of pharmacy on a par with that in other civilized countries.

THE FACULTY OF TROPICAL MEDICINE AND HYGIENE, BENGAL

At the examination for the diploma of Tropical Medicine (D. T. M. Bengal), held at the Calcutta School of Tropical Medicine in April 1934, the following 32 out of 36 candidates were successful:

Passed

(Arranged in alphabetical order)

- Brajendra Chandra Aich, M.B. (Cal.), private practitioner.
- Hari Pada Banerjee, M.B. (Cal.), D.P.H. (Cal.), private practitioner.
- Jadab Lal Banerjee, M.B. (Cal.), private practitioner.
- Lalit Kumar Banerji, M.B. (Cal.), private practitioner.
- Jnanendra Nath Basu, M.B. (Cal.), worker, health department, Calcutta Corporation.
- Provash Ranjan Bhattacharyya, M.B. (Cal.), D.P.H. (Cal.), private practitioner.

- Rasamay Bhattacharyya, L.M.P. (Assam), assistant medical officer, Bokpara Tea Estate, Upper Assam.
- Sailendra Nath Chattopadhyaya, M.B. (Cal.), D.P.H. (Cal.), private practitioner.
- Subal Chandra Chattopadhyaya, M.B. (Cal.), medical officer, Presidency Jute Mills, Rishra, E. I. Railway.
- Subal Chandra Das, M.B., B.S. (Patna), private practitioner.
- Rameshwar Dayal, M.B. (Cal.), Civil Assistant Surgeon, Government of Bihar and Orissa.
- Lal Rajendranath Shah Deo, M.B., B.S. (Patna), private practitioner.
- Jean Arthur Gemmell, M.B., Ch.B. (Edin.), Women's Mission Hospital, Ajmer Raj.
- Basanta Kumar Ghosh, L.M.F. (Bengal), M.B. (Cal.), private practitioner.
- Nani Lal Ghosh, M.B. (Cal.), private practitioner.
- Rash Gour Ghoshal, M.Sc., M.B. (Cal.), private practitioner.
- Syed Mahmud Hassan, M.B., B.S. (Patna), private practitioner. (Selected for appointment to Bihar and Orissa Provincial Medical Service.)
- Mangesh Narayan Kalbag, M.B., B.S. (Bom.), Captain, A.M.O., medical officer, Co-operative Hospital, Hubli.
- Huai-chieh Kan, M.D., College of Medicine, National Central University, Nanking, China.
- Anil Mukherji, M.B. (Cal.), D.P.H. (Cal.), private practitioner.
- Bodapati Lakshmi Narasimha Rao, L.M.S., assistant pathologist, Osmania Hospital, Hyderabad, Deccan.
- Allen Albert Morris Nolan, I.M.D., Assistant Surgeon, Government of India.
- Norman Charles Parfit, B.M., B.Ch. (Oxford), private practitioner.
- Amrik Singh Pruthi, L.S.M.F. (Punjab), medical officer, Rewat (Rawalpindi).
- Donald Robertson, M.B., Ch.B. (Edin.), medical officer, Mission Hospital, Udaipur.
- Saradindu Kumar Sen, B.Sc., M.B., B.S. (Patna), private practitioner. Awarded the first prize in entomology.
- Tulshi Charan Sett, M.B. (Cal.), private practitioner.
- Surendra Amrit Sharma, M.B. (Cal.), private practitioner.
- Nanda Lal Sinha, M.B. (Cal.), private practitioner.
- Moni Mohan Sircar, M.Sc., M.B., D.P.H. (Cal.), private practitioner.
- Tara Singh, L.S.M.F. (Punjab), L.T.M. (Bengal), private practitioner.
- Yuen-Yo Ying, M.D. (Hunan), L.T.M. (Bengal), Assistant Professor of Medicine, National College of Medicine of Shanghai, China. Awarded the 'Chuni Lal Bose' Gold Medal.

HAILSHAM CHILDREN'S HOME

EUROPEAN exiles in the tropics are sometimes faced with the problem of finding suitable accommodation for their infants or young children.

The 'Children's Home' which has just been opened at Hailsham near Eastbourne by Mr. and Mrs. R. B. Stewart provides an admirable solution.

The 'Home' is situated at an altitude of 500 feet above sea level and faces the south-west. Mrs. Stewart has had several years of experience as a nurse at the famous Great Ormond Street Children's Hospital, and in private work. Among those to whom reference may be made are Miss Tisdale, Matron of the Great Ormond Street Hospital, and Colonel R. M. Green and Major-General Sir John Megaw both retired I.M.S. officers who were well known in India.

The terms are moderate, ranging from two to four guineas weekly according to age and other conditions.

Applications are received by Mr. R. B. Stewart, 'Boynnton', Western Road, Hailsham, Sussex.

The Serum Treatment of Cerebrospinal Fever

By A. FLEMING, F.M.C.S.

and

G. F. PETRIE, M.D.

(Abstracted from *Recent Advances in Vaccine and Serum Therapy*. J. and A. Churchill, London, 1934, p. 130)

DOSAGE AND MODES OF ADMINISTRATION OF THE SERUM

Intrathecal route.—Daily injections of from 30 to 60 c.cm. for adults and from 10 to 20 c.cm. for infants are recommended, and at least four doses in all should be given; the amount of the dose should be less than that of the cerebrospinal fluid which is withdrawn; and the serum should be warmed to body temperature and introduced into the spinal canal by the gravity method at the usual site for lumbar puncture. In order to lessen the risk of a relapse, two or three additional doses of serum should be given after the meningococci have disappeared from the cerebrospinal fluid; and it is advisable to perform several lumbar punctures with the object of promoting drainage of the fluid after the serum treatment has been stopped. According to Neal, the average sporadic case requires 6 to 10 doses of serum; these cases are considered by her to be less severe than those which occur in times of epidemic prevalence. Early administration of the serum is of great importance, since there is abundant evidence that the fatality rate is least among patients whose treatment by serum is begun within the first three days of the illness. Full details of the technique of administration of the serum are given in the memorandum on cerebrospinal fever which has been issued by the Ministry of Health.

Combined intrathecal and intravenous or intramuscular routes.—Herrick maintained that a bacteriæmia is often present and that the meningitis is a secondary complication of the disease; he therefore recommended that the intrathecal injections should be supplemented by large doses of serum given intravenously. The general opinion, however, is not favourable to this practice, except in cases that are predominantly bacteriæmic. Neal is critical of the data on which Herrick based his belief that intravenous treatment improved the clinical results; other workers have seen dangerous reactions follow the method in some patients in spite of negative cutaneous and conjunctival tests for hypersensitiveness and one worker thought that in two patients the intravenous injections predisposed to a fatal issue. Banks has used the method in a small number of cases, and has been favourably impressed by the results; in his experience immediate serum reactions do not occur and even large doses are well tolerated, in this respect contrasting with the reactions that may follow the intravenous injection of diphtheria antitoxin. Nevertheless, the relatively slow course of the disease with the gradual production of antibodies in the blood may increase the tendency to severe allergic reactions, when the serum is given intravenously at the end of the first week or later in the illness. If the physician should wish to supplement the intrathecal doses, intramuscular injections possess the advantage of seldom causing reactions of this kind, and are doubtless almost as effective as intravenous doses.

Intracisternal route.—Of late years, and particularly in the United States, the method of injecting the serum into the cisterna magna—the subarachnoid space bounded by the inferior surface of the cerebellum, the posterior surface of the medulla, and the occipito-atlantal ligament—has been employed to a considerable extent. It appears to be free from danger, but should

not be undertaken without previous practice on the cadaver. The introduction of serum by this route is believed by some physicians to be necessary when the condition of spinal subarachnoid block exists. The condition is most often due to the presence of a thick exudate in the spinal canal, or to subarachnoid adhesions. It may be diagnosed when only a few cubic centimetres of an extremely purulent fluid which has a low pressure are obtained by lumbar puncture, and when at the same time a copious flow of fluid under tension is obtained by cisternal puncture. Ebaugh prefers alternate injections of the serum by the cisternal route and by lumbar puncture; eight patients who were in an extremely critical condition on admission to hospital were thus treated, and five of them recovered. If the cerebrospinal fluid is fibrinous, the subarachnoid space should be irrigated with Ringer's solution by flushing the space through the needle in the cisterna, and also by allowing the solution to flow between the needle in the lumbar theca and the one in the cisterna. Some regard cisternal puncture as an easier method in competent hands than lumbar puncture, and think it is better tolerated by the patient. To a patient with fulminating meningitis he gave fifteen injections, the total dosage amounting to 219 c.cm.; of these injections eleven were cisternal, three spinal, and one intravenous; complete recovery followed. A series of 69 cases, with a fatality rate of 17.4 per cent has been reported by Fox; patients with the fulminating form of the disease who died within a few hours of admission to hospital are not included in the series. The average amount of serum given to each patient was 190 c.cm.; 19 per cent of the total amount of serum administered was given intravenously, 24 per cent intramuscularly, 24 per cent intrathecally, and 33 per cent intracisternally. There was an average of five lumbar and five cisternal injections for each patient.

A comparison between the results of serum treatment by the cisternal and the usual lumbar route has been made by Goldman and Bower. They treated 48 patients by the lumbar route with a fatality rate of 52 per cent; and 43 patients by the cisternal route with one of 25.5 per cent; patients who died within 24 hours after their admission to hospital are not included in these figures.

Some workers believe that thorough irrigation of the spinal canal with saline is a valuable adjunct to serum treatment and that the additional trouble is justified by the improved results which follow. Thus Whittingham and his colleagues preferred this plan to the method of producing an increase in the intrathecal pressure by giving a general anaesthetic, as recommended by Flaek, and were impressed by its beneficial effects in toxic and comatose patients.

Intraventricular route.—This method has not been much used, and it is doubtful whether the results are encouraging. Neal prefers the ventricular to the cisternal route when there is obstruction to the flow of the cerebrospinal fluid; she hopes by this means to avoid the risk of pressure upon the medulla. A large experience of cerebrospinal fever in New York has led her to advise the very cautious introduction of the serum by lumbar puncture when, owing to a spinal block, there is no flow of fluid; if this plan does not succeed, resort may be had to ventricular puncture. She favours conservative rather than such intensive methods of serum treatment as intrathecal injections given every 8 or 12 hours, or injections by other routes. In young infants ventricular puncture is best performed through the anterior fontanelle. Lyon thinks he has obtained good results by introducing serum into the ventricles and at the same time withdrawing fluid from the spinal subarachnoid space; the method is particularly useful in infants with a patent anterior fontanelle.

THE SERUM TREATMENT OF CEREBROSPINAL FEVER IN INFANTS AND YOUNG CHILDREN

Opinion is unanimous that the disease is almost always fatal in infants less than one year old, when serum is not

given to them. Among the large number of cases of meningococcal meningitis observed by Neal and Jackson in New York there were twenty-five among infants within the first three months of life. The treatment included daily injections of serum by the lumbar route, and, when there were definite signs of block, ventricular or cisternal injections were also given; of 23 of these patients, eleven died (47.8 per cent). McLean and Caffey treated 11 children, who were suffering from the sporadic type of the disease and who had symptoms of obstruction of the subarachnoid space, by introducing serum into the ventricles and the cisterna; eight completely recovered. On the other hand, McKhann found that, although the symptoms often diminished in severity when serum was given alternately into the ventricles and into the lumbar subarachnoid space, death ultimately followed from chronic hydrocephalus. Benjamin recommends early intensive treatment by the intravertebral routes combined with intravenous and intramuscular injections.

The tendency of the present time is to pursue energetic treatment in critical cases. For example, Peet gives details of the treatment of a girl, aged eight years, to whom 790 c.cm. of serum was administered: 560 c.cm. by eighteen lumbar punctures; 155 c.cm. by six cisternal punctures; and 75 c.cm. by four ventricular punctures; the child made a perfect recovery. In the opinion of this author cisternal and ventricular punctures and injections will do much to prevent hydrocephalus. The benefit derived from injections by these routes may conceivably be due in part to the drainage of the cerebrospinal fluid, and this makes it difficult to apportion the share of each factor in the final result. That drainage of the fluid may do good apart from serum treatment is shown by the case of a child of five months who was under the care of Mackay; she performed twenty-one ventricular punctures, from 50 to 100 c.cm. of fluid being withdrawn at each puncture, the last on the fifty-third day of the illness. A considerable leak took place on one occasion through the puncture wound, and from that time the condition of the child began to improve and the circumference of the head to diminish. A method has been reported from Germany which gives further evidence of the tendency to institute drastic treatment for the disease in children. In brief, it consists in removing as much as possible of the cerebrospinal fluid by lumbar puncture and replacing it by air. Warmed serum is then injected until air can no longer be aspirated. The advantages of the method are said to be the removal of the infecting organisms with their toxins and the circumstance that the serum escapes dilution by the cerebrospinal fluid, and is thus enabled to come into better contact with the affected portions of the brain and the spinal cord.

The Treatment of Pruritus Ani

By H. deLISLE CRAWFORD, M.D., M.Ch., F.R.C.S.I.
(From the *Practitioner*, Vol. CXXXI, No. 5,
November 1933, p. 621)

THE following treatment for this most distressing condition is based on the principle of keeping the area as dry as possible and employing effective and non-irritating antiseptics:—(1) As an aperient liquid paraffin only; (2) after evacuation and at regular intervals thorough cleansing with cold water and coal tar soap; (3) thorough drying with a soft towel; (4) introduction of a little adrenaline ointment into the anal canal if piles are present; (5) a teaspoonful of 1-1,000 acriflavine emulsion in paraffin rubbed gently into skin; (6) as soon as irritation is checked talc powder of any good brand is used freely instead of acriflavine.

Almost every case I have seen in the past year has yielded in a few days to this treatment and has been cured within a fortnight; one case has lasted

a month but none were of longer duration though quite severe. To get results quickly the various details must be carried out with the greatest care and patience.

The Choice of an Anæsthetic in Complicated Obstetrical Cases

By SAMUEL JOHNSTON, M.A., M.D.

(Abstracted from the *Canadian Medical Association Journal*, Vol. XXIX, October 1933, p. 399)

Heart lesions.—Heart lesions seldom veto the giving of a general anæsthetic, but these cases require careful selection of the drugs and methods used. In mitral disease, if the pulmonary circulation is interfered with and œdema, cough, dyspnoea or cyanosis are present, nitrous oxide and oxygen with a high percentage of oxygen would be the anæsthetic of choice, with pre-medication with atropin. Although I am not an advocate of chloroform, a mixture of chloroform and ether, supplemented with oxygen, might be used in these cases. The presence of a mitral murmur, with no evidence of failure of compensation, would not contraindicate nitrous oxide and oxygen and ether. One must not forget however that in all pulmonary disease, whether it is a primary condition or a result of mitral disease, the administration of ether over a long period of time may lead to œdema of the lungs. Mitral stenosis is always a serious complication, and faulty administration of the anæsthetic may lead to dilatation of the left auricle. My choice here would be ether and oxygen, if there are no contraindications, or rectal oil-ether anæsthesia.

In aortic disease, anæsthesia should be induced with the greatest care, avoiding struggling or excitement. Pre-medication should be given in these cases, 1/6 to 1/4 gr. of morphine with 1-200 gr. of atropin, administered three-quarters of an hour before the anæsthetic. If morphine is contraindicated, 1/12 gr. of heroin may be used. Nitrous oxide and a high percentage of oxygen for induction, sustained by ether by the drop-method, is the preferable anæsthetic in prolonged operations. For short anæsthesia nitrous oxide and oxygen with ether may be used throughout. It is all-important that cyanosis does not occur. It must be remembered that these patients are liable to syncope when returning to consciousness and require great vigilance until they have completely recovered from the anæsthetic. They should not be allowed to sit up for some time, as should retching or vomiting occur there may be an alarming fall in the blood pressure.

Where there is cardiac decompensation in pregnancy it is well to keep in mind that blood-pressure findings are quite as important as the heart examination, for there is never return of compensation with a falling blood pressure. Also the amount of hæmoglobin must not be overlooked, as in anæmic conditions the oxygen-carrying capacity of the blood is reduced, making greater cardiac effort necessary. In the selection of the anæsthetic, the type and general condition of the patient, the position of the child, the condition of the cervix and the size of the pelvis must be considered. Not only the kind of anæsthetic but the amount necessary must be taken into consideration, with reference to the oxygen needs and the time required for operation. In this connection the length of the anæsthetic administered is very important, as the administration of nitrous oxide and oxygen for the time required for the performance of a Cæsarean section is much less dangerous for the patient than the shorter period of surgical anæsthesia necessary for a difficult forceps operation when the patient has had several hours of trying labour. In routine cases of decompensation, my choice of anæsthetic would be nitrous oxide and oxygen and ether with a high percentage of oxygen.

Where there are structural changes in the myocardium, such as myocarditis or fatty degeneration, the

anæsthetic danger is greatly enhanced, as an extra strain is imposed on the already weakened and diseased heart. In these cases, ether is the anæsthetic of choice, with a careful induction with nitrous oxide and oxygen. It has been my custom to use oxygen continuously with the ether. The danger lies in giving the patient too much ether. Hypertrophied or dilated heart conditions would call for the same treatment as I have just described.

In all abnormal heart conditions, care must be taken not to frighten the patient by putting the mask on the face too quickly, or using too much concentration of the drug employed for anaesthesia. Have the drug well diluted with air or oxygen, proceeding slowly with the administration. Cyanosis must be avoided.

Tuberculosis of the lung.—In these cases the air passages must not be irritated or the respiration or circulation stimulated more than can be helped. The greatest possible care, therefore, must be taken both in the choice of an anæsthetic and in the method of administration. Ether is contraindicated. Nitrous oxide and oxygen, with some form of pre-medication—morphine and atropin, or heroin and atropin, with the addition of nembutal with nervous patients—is the anæsthetic of choice. Spinal anaesthesia would be my second choice, with pre-medication the same as before nitrous oxide and oxygen. Chloroform would be my third choice, but with this drug no previous medication would be used.

Diabetes.—Here chloroform should be avoided, but if for some reason it has to be given, the dosage should be light, and if possible oxygen should be administered with it. The anæsthetic of choice in diabetic cases is nitrous oxide and oxygen. Spinal anaesthesia is often used with excellent results. Where nitrous oxide and oxygen is given, some pre-medication is usually necessary—morphine, heroin or nembutal, or a combination of nembutal and one of the other two drugs.

In spinal anaesthesia, usually smaller doses are required—50 to 100 mill. novocaine. With operative procedure, a larger dose of the spinal anæsthetic is necessary, and the same pre-medication as for nitrous oxide and oxygen anaesthesia may be required. The site for injection of the spinal anæsthetic in these cases is preferably between the third and fourth lumbar vertebrae.

Ether may be given if nitrous oxide and oxygen or spinal anaesthetics are not available. This drug must be carefully administered so as not to saturate the patient with it. Ether should always be given by the open method in these cases, as otherwise the patient is liable to develop acetonæmia or acetonuria. Where possible, oxygen should always be administered with ether.

Hæmorrhage.—My choice of anæsthetic in case of hæmorrhage is nitrous oxide and oxygen, with if necessary the addition of ether. In these cases the carrying power of the blood is greatly lessened and a high percentage of oxygen is necessary. Where respiration is embarrassed 5 to 10 per cent carbon dioxide should be administered at intervals with the oxygen. These patients take ether with oxygen added fairly well. It is the duty of the anæsthetist to see that remedies such as glucose and saline are ready to be given intravenously, and, in severe cases, preparation for transfusion should also be made.

Toxæmias.—The more important toxæmias are: eclampsia, pernicious vomiting, chorea gravidarum, hydræmia and albuminuria.

Before the administration of the anæsthetic it is very important that one should satisfy oneself that the stomach is empty, and often a lavage of the stomach is necessary; a mild sedative is very helpful to enable this to be done. Chloroform should be avoided, on account of its narrow margin of safety in regard to respiratory and cardiac paralysis. It often leads to necrosis of the liver. Ether is much safer than chloroform but it is not the anæsthetic of choice. Nitrous oxide and oxygen, in the hands of those who

know how to administer it, is the safest anæsthetic for mother and child. To this, a small amount of ether may be added if more relaxation is required.

Spinal anaesthesia is also to be recommended, though it is contraindicated in cases with very high or very low blood pressure and when patients are exhausted from hæmorrhage or pernicious vomiting, or when there are other contraindications. In spinal anaesthesia the uterine contractions seem to be lessened or abolished, in which case, pituitrin is given. If the spinal injection is too high it affects a large number of the white rami communicantes of the cord, and thus more completely blocks the efferent inhibitory impulses of the sympathetic ganglia. The spinal anæsthetic should be given between the third and fourth lumbar space.

In an eclamptic condition 20 cubic centimetres of 10 per cent magnesium sulphate has greatly aided the anæsthetist and has been used with good results. I might add that in many of these complicated obstetrical cases a local anæsthetic, either alone or with the addition of nitrous oxide and oxygen could be used with good results.

After all, while we may lay down a general principle in handling these cases, each must be dealt with on its individual merit, and it seems to me that the ultimate result depends not only in the choice of the anæsthetic agent used and the technique employed but also on the skill of the anæsthetist and his co-operation with the obstetrician.

Carbon Dioxide and Oxygen in Obstetrics

By W. T. McCONNELL, M.D.

and

RONALD L. McCORMACK, M.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. CI, 2nd December, 1933, p. 1783)

CURRENT literature teems with the controversy between a group of investigators who contend that carbon dioxide is superfluous and harmful to the asphyxiated newborn infant and another group who claim that oxygen alone is not entirely adequate for resuscitation of asphyxia neonatorum. It is our conclusion after clinical investigation and diligent perusal of the literature that both groups are right as far as they go but that the common ground between them, the use of adequate and intelligently varied mixtures of carbon dioxide and oxygen, will give the desired result in resuscitation when nerve cells of the centre have not been deprived of the minimum supply of oxygen and carbon dioxide for the maintenance of foetal existability.

Three years of oxygen administration (1928—31) with some means of artificial respiration failed to decrease the mortality rate in the asphyxias or to overcome atelectasis, the forerunner of pneumonia. Carbon dioxide alone was obviously not used; but the use of variable mixtures of carbon dioxide and oxygen, from 5 to 30 per cent of carbon dioxide with a full complement of oxygen, for the past two years in our practice of obstetrics and treatment of the newborn enables us to say that we have not failed to resuscitate a single asphyxia patient except one with cerebral hæmorrhage and one with a congenital abnormality of the heart. Both infants were premature. We have had no atelectasis that was not easily controlled with the mixtures and have had no subsequent bronchitis or pneumonia. Similar treatment of the newborn in the obstetric service at the Louisville City Hospital, for the past year has yielded equally good results in respect to neonatal pulmonary complications.

An understanding of the physiology of respiration and the pathology of asphyxia is a prerequisite to the intelligent administration of the gases, and the results are in direct proportion to the degree of such understanding. The ready-made mixtures of 5, 7 or 10 per

cent of carbon dioxide with their complement of oxygen are safest for the average physician, but they cannot be applied with success in all cases, for we have found that, as a rule, the greater the degree of asphyxia and lowered excitability of the centres, the higher the percentage of carbon dioxide necessary for stimulation. The classic differentiation of asphyxia, livida and pallida, are examples, the pallida being simply a greater degree of asphyxiation and requiring higher percentages of carbon dioxide for stimulation. The laryngeal reflex used as a means of distinguishing the degree of asphyxia has never been used by us, as we feel that it is a waste of time. It is easy to insert a tracheal catheter if response to the mixtures of 20 or 25 per cent carbon dioxide is not shown within a few seconds. When mixtures above 5 per cent are used they must gradually be lowered as response increases, so that the respiratory efforts of the child will be stimulated only slightly above normal action. The mixtures should never be given strong enough to cause a gasping, struggling, straining type of respiration. The objective symptoms are the guide, and the nearer the normal respiratory rate the treatment can be carried out, the longer it can be kept up and the more oxygen can be furnished to the tissues.

It has always been our idea to use carbon dioxide as a vehicle for oxygen supply to the tissues. Coryllos has shown that oxygen passes more quickly from the air sacs to the blood when a small percentage of carbon dioxide is present.

Our routine neonatal treatment of premature infants includes the administration of 5 per cent of carbon dioxide and 95 per cent of oxygen into a tent for a few minutes three times a day. The length of time of each treatment is determined by the respiratory response of the patient, but the average is about fifteen minutes.

The development of shock during anaesthesia and following the emptying of the uterus is mainly due either to the anaesthetic or to fatigue, or to both. The cause in both instances is ultimately the same, for to the acidosis and paralysing effect of the anaesthetic is added the increased lactic acid production of the maternal tissues with displacement of carbon dioxide from the base.

If the degree of acidosis is sufficient to produce a mild degree of shock with splanchnic endorsement, an insufficient amount of oxygen and carbon dioxide is supplied to the uterine muscle to oxidize its excessive load of lactic acid. A local acid base imbalance remains and increases in the smooth muscle cells with subsequent shock and loss of tone of the uterine muscle, and postpartum hemorrhage then occurs.

All of the mechanical methods of control of postpartum hemorrhage cause an ischemia of the uterine muscle, thereby defeating any possibility of immediate restoration of function. Therefore the treatment of postpartum hemorrhage resolves itself into the treatment of shock. The administration of carbon dioxide and oxygen, by decreasing the primary acidosis, elevates the general nervous tone and accelerates circulation, thereby re-establishing normal tone and function of the uterine muscle.

In shock due to anaesthesia, the administration of carbon dioxide and oxygen stimulates the respiratory centre, causing an increase in respiratory depth and rate, thereby furnishing more oxygen to the haemoglobin, relieving acidosis, stimulating the heart muscle, accelerating circulation and elevating tissue tone.

Something more than one year ago our attention was called, in a rather unique manner, to a possible effect of carbon dioxide inhalations as a stimulant to uterine contractions during labour. A private patient who had been having a prolonged first stage with weak, irregular contractions was developing uterine inertia. We thought it likely that she was having a fatigue acidosis and decided to administer several inhalations of carbon dioxide and oxygen to see what clinical effect we would get in combating the fatigue.

After a few inhalations we noticed that the uterus began a good contraction, followed by adequate relaxation. After this contraction, we gave the patient a few more inhalations and were gratified to see the contractions occurring with good regularity and force. Our impression was that the carbon dioxide had stimulated normal uterine contractions with normal relaxation periods. Recognizing the possibility of these phenomena being coincidental, we employed the same procedure in every case of inertia and found a uniformity of response that removed any reasonable doubt as to its effect as a stimulant. Further observations substantiated our results.

Among the inertia patients at the City Hospital were a number who had received caudal anaesthesia, and in these the response was much slower. Our best results were obtained in inertia caused by fatigue or that developing in connection with the administration of such drugs as morphine, sodium amytal, nembutal and chloroform.

As soon as it seemed fairly well established that carbon dioxide actually did have a stimulating effect on uteri suffering from inertia during labour, we decided to employ it in those cases of excessive bleeding due to inertia following the expulsion of the placenta. Ordinarily there will be only normal bleeding if contractions during the third stage have been strong enough to expel the placenta spontaneously. But there is a certain percentage of cases in which some degree of shock occurs after a physiologic third stage, owing to relaxation of the patient following prolonged, tiring labour, or associated with some form of anaesthesia. The degree of shock in most of these cases is so slight that the relaxation of the uterus is the only clinical evidence of depression; or it may rarely become sufficiently severe to have the clinical picture of surgical shock. We feel that, from our observations this mild form of shock is the cause of more postpartum hemorrhage than has hitherto been thought.

In our private work we have adopted the plan of administering a few inhalations of carbon dioxide and oxygen immediately following the expulsion of the placenta and have had no undue bleeding from the placental site in any of these cases in two years. In the City Hospital we have, for the past several months, employed carbon dioxide and oxygen inhalations as a routine in all cases of profuse bleeding from the placental site following the expulsion of the placenta. Records on twenty-five such cases show uniformly good results.

In two cases a certain degree of shock was a demonstrable complication of the bleeding, and in another a toxic condition with acute pulmonary oedema accompanied the hemorrhage.

In a certain percentage of cases of eclampsia the toxemia becomes so severe that a paralysing effect on the cardiovascular system takes place, with the result that the elevated blood pressure drops rapidly to far below normal limits, the pulse becomes very rapid and thready, and pulmonary oedema quickly develops. The patient becomes cold and sweaty, the respirations become slow and shallow, and she dies of the depressive influence of the toxin. We have employed carbon dioxide in five cases of this type with prompt recovery in three. In the two cases in which death resulted, autopsy showed a severe coexistent infection, in one case a well established pneumonia and, in the other, liver abscesses. Both patients had developed postpartum eclampsia in the home and were brought into hospital after a long delay.

Abdominal distention following Caesarean section is due to shock, paralysis of the splanchnic nervous system, loss of smooth muscle tone and decrease in local circulation. Pressure in the intestine aggravates the condition. An increase in carbon dioxide tension has long been known to stimulate smooth muscle activity. Therefore one would expect the administration of carbon dioxide and oxygen to stimulate peristalsis and restore normal cellular function. We have found in our work that this hypothesis is borne

out by clinical results. Our records show that the gas mixture was used in sixteen consecutive cases with success.

CONCLUSIONS

1. From 1928 to 1931, oxygen therapy was applied to all the conditions described, without any appreciable change in morbidity or mortality.

2. Carbon dioxide and oxygen mixtures, when administered by the metric control system, have been adequate for the relief of asphyxia neonatorum, and atelectasis neonatorum and its sequelae over a period of two years.

3. Carbon dioxide and oxygen mixtures safely and promptly combated uterine inertia in the first stage of labour.

4. The classic mechanical treatment of postpartum hæmorrhage does not stand up under physiologic investigation. Hæmorrhage is evidently due to postpartum acidosis of the uterine muscle. Carbon dioxide and oxygen controlled twenty-five consecutive cases.

5. The abdominal distention following Cæsarean section was promptly relieved in sixteen consecutive cases, even after thirty-six hours' duration in one instance.

6. The practical points in symptomatic administration are that treatment will usually be started with mixtures of between 20 and 30 per cent of carbon dioxide with oxygen. This high percentage is only for stimulation of the respiratory centre and must be promptly reduced, after a few inspirations, to the percentage that will maintain a normal or slightly higher respiratory rate. Strict regard must be paid to the fact that even 5 per cent of carbon dioxide and 95 per cent of oxygen will overstimulate in some cases and should then be used for only a few minutes at a time.

Treatment of Leprosy

Abstract Reviews

(Abstracted from the *Prescriber*, Vol. XXVII, 1933, No. 11, p. 349)

DISCUSSING the modern treatment of leprosy, Cochrane (London) says that the first question to decide is whether a case is one which will benefit from treatment. Modern developments indicate that the disease is self-healing. Like tuberculosis, leprosy may become arrested at any point, and it is essential to recognize the signs of activity. Active cases are those in which there are clinical or microscopical evidences of progressive or of recessive changes in lesions, with or without accompanying systemic disturbances. These evidences include: positive bacteriological findings in skin or mucous membrane; the presence of raised or erythematous lesions; increase or diminution of lesions in size or number; tenderness of nerves, with or without thickening. Before one can treat leprosy with any hope of success it is essential first to treat any other disease that may be present. Modern treatment of leprosy is based on the specific action of hydnocarpus (chaulmoogra) oil, which may be used in several forms: (1) iodized or creosoted esters; (2) alepol; (3) plain oil with creosote. The choice depends chiefly on the cost of the remedy and the ease in obtaining it. In early nerve cases the drug is injected subcutaneously or intramuscularly in doses beginning with 2 cubic centimetres and rising by weekly injections to 12 cubic centimetres. Cutaneous leprosy presents more difficulties, and here again the method of choice is the esters of hydnocarpus given intradermally. Lepa reaction, the condition caused by the breaking down of leprotic foci, is met by stoppage of injections, giving a purge, and administration of tartar emetic. Eye reactions demand care in general treatment and the use of alkaline washes. Gold preparations have a

limited place in treatment, and of these solganal B is preferable.

Strachan (Basutoland Leprosy Colony) reports on treatment with chaulmoogra oil. So much of this treatment, he says, has been inadequate that little can be said for or against it. The percentage of arrests in early cutaneous cases was only 21.43, while in early nerve cases it rose as high as 79.25. Over 50 per cent of early nerve cases recover without special treatment provided the patients are brought into a favourable environment, with good nutrition, hygiene, and physical exercise, the special treatment of predisposing or concurrent diseases (syphilis, etc.) being of prime importance.

Muir (Calcutta) emphasizes the greater activity of intradermal than of intramuscular injections in the administration of hydnocarpus preparations, the ethyl esters of which he prefers as they are less quickly absorbed. The esters are non-irritating when they are mixed with 4 per cent of creosote. If the oil is slightly warmed, it is possible to give a hundred punctures of about half a minim each, infiltrating some 5 or 6 cubic centimetres in an area of 14 square centimetres and when the oil is given in this way the initial reaction soon passes off. Lagrosa (Philippine Islands) describes a trial of weekly intradermal injections of iodized ethyl esters, and concludes that the local treatment of anæsthetic areas has definite value, return of normal sensibility occurring in favourable cases, with the advantage of possible prevention of neuritic changes.

The use of alepol, a sodium salt of the lower melting-point fatty acids of hydnocarpus oil (sodium hydnocarpate), is reported on by Dikshit (Vizagapatam Medical College). It has a less irritant effect than other preparations of hydnocarpus, and its hæmolytic action may be diminished by dissolving it in Locke's solution. In the early stages it is given by intramuscular injection (3 per cent); later the intravenous route is employed (1 and 2 per cent). The greatest improvement was seen in nerve and cutaneous cases; the cutaneous cases become stationary and improve very gradually, becoming bacteria-negative after a few months' treatment. Alepol is reported on favourably also by Bhandari (Gorakhpur), who finds it to be well tolerated and less irritating than other preparations of hydnocarpus. Badenoch and Alfred report on the use of alepol tabloids. These were given twice weekly, one the first week, two the second, and three the third. The tabloids were well borne, and gave good results, especially when combined with intradermal injection of iodized esters.

The pharmacology of alepol is the subject of a study by Dikshit (Vizagapatam). It has a low toxicity as compared with other soaps of hydnocarpus oil. It inhibits the growth of tubercle bacilli and exerts some toxic action on certain helminths. It has a marked hæmolytic action, which may be lessened by dissolving in Locke's solution, a process which also makes it less irritating. Large doses depress the cardiovascular system and stimulate respiration. Oral administration leads to gastro-intestinal irritation, but movements of the gastro-intestinal tract are little affected by intravenous administration. A study by Rao (Purulia Leper Colony) indicates that injection of any hydnocarpus preparation is followed in all types of cases by marked increase in the serum globulin.

A warning is uttered by Canaan (Jerusalem) to the effect that extreme care is necessary in the administration of potassium iodide, a matter which has been repeatedly emphasized in these reviews. In the hospital at Jerusalem it has never done anything but harm. The tubercles that form under its influence show an exceptional crop of bacilli, and he thinks it is too dangerous to be used at all. In a recent review (*Prescriber*, 1931, Nov., 381) it was stated that the dosage of iodides must be very carefully estimated, as the reaction, if severe, may cause further dissemination of bacilli.

The use of the organic salts of gold, solganal and solganal B, is recorded by Alfred (Leprosy Settlement, F. M. S.). Fifteen weekly doses ranging from 0.1 to 0.5 gramme were given in ten cases, solganal intravenously and solganal B intramuscularly. In cases known to react readily a desensitizing dose was given, and with this precaution the drug was found to be quite safe. The cases selected were those showing leprosy lesions of the eye, and the results were: improved six, no change four, worse one. The results appeared to be better in Chinese than in Indian patients.

Jackson (Bankura Leprosy Home) reports a study of the influence of hydrogen-ion concentration on pain reaction in the subcutaneous administration of sodium hydnocarpate solutions. He finds that there is no definite relationship between these factors, those having a low pH giving much the same results as those of high alkalinity as regards pain reaction. In another communication the same worker reports that addition of glycerine to solutions of sodium hydnocarpate for subcutaneous infiltration is of considerable benefit in reducing the pain reaction, which is liable to vary with different samples of the salt.

A new antimony compound has been tried in four hospital cases (two maculo-anæsthetic and two nodular) by Kingsbury (New York). This is 3 : 3-diamino-4 : 4-dihydroxy-arsenostibino-benzene, and is known as 'M 103'. It is soluble in water and has an acid reaction. Alkalinized by means of sodium hydroxide it forms a disodium salt, which is diluted with normal saline to represent 0.1 gm. in 10 cubic centimetres. This solution is given intravenously and is well borne. The first case was apparently cured; two cases showed moderate improvement, and in the fourth case the disease appeared to be arrested. Kingsbury thinks that this preparation is superior to the ethyl esters of chaulmoogra oil.

Mercurochrome has been tried in a number of cases by Muir and Chatterji (Calcutta). In many patients it effects marked improvement in dermal infections, pyorrhæa, bowel conditions, and general health, while its effect in relieving the lepra reaction is spectacular and often immediate. Mercurochrome should be given intravenously in 1 per cent solution, the dose for an ordinary adult being 3 cubic centimetres rising to a maximum of 10 cubic centimetres. Injections may be given once a week, but if no reaction occurs after the first dose 5 cubic centimetres may be given three days later. Benefit may be observed early in the course (five or six doses), but this is usually delayed until the maximum dose is reached. A flare-up usually occurs at the site of septic infection, but this passes off in a few days and becomes less with subsequent injections. Should any sign be observed of recrudescence of acute symptoms, apart from such reaction, mercurochrome should be discontinued; increase in the blood sedimentation rate is another indication for stoppage of the treatment. Mercurochrome is of no value in the treatment of leprosy itself; it merely removes concurrent infections. A similar report by Rao and Roy (Purulia Leprosy Colony) confirms these results in respect of certain concurrent infections.

The use of brilliant green is described by Ryles (India). He uses a combination of this dye with crystal violet, known as 'Bonney's blue', which has the following composition: brilliant green 0.5 gramme, crystal violet 0.5 gramme, alcohol 25 cubic centimetres, distilled water to 2,500 cubic centimetres. This is given by intradermal injection, in the same way as with hydnocarpus oil, in doses of 5 to 8 cubic centimetres. Should the injections prove painful, 1 per cent of procaine may be added. Of 211 patients on whom this treatment was tried, 125 were definitely better on brilliant green than on oil; 19 did better on oil; 29 were equally benefited by both, and 28 were not improved by either. There appear to be no contraindications to this dye treatment, and Ryles regards

the results as being at least as good as those obtained from hydnocarpus oil.

Treatment of leprotic ulcers by periarterial sympathectomy is described by Black (Singapore). He has performed this operation in fifteen cases of leprosy. The ulcers were on the feet and were all of old standing—from eight months to twelve years—and had resisted all ordinary methods of treatment. In every case the operation led to complete healing of the ulcers, the process taking from one to eight weeks. In six cases relapses occurred, but one soon healed with further rest in bed. The cause of relapse appeared to be the patients' habit of getting out of bed too soon. In the successful cases the ulcers have remained healed for periods ranging from four to fifteen months.

A Fatal Case of Phrenic Avulsion A Memorandum

By MAURICE CASSIDY, C.B., M.D., F.R.C.P.

and

R. O. LEE, M.B., F.R.C.S.

(From the *British Medical Journal*, 14th October, 1933, p. 684)

PHRENIC AVULSION is usually regarded as being a trivial operation. This particular patient was told that, though we could not promise him that the operation would improve his condition, we thought that it would probably do so, and that in any case the procedure was devoid of risk. We feel bound to put this case on record, demonstrating as it does that phrenic avulsion is by no means devoid of risk. A preliminary postural drainage or bronchoscopic lavage would probably have saved this patient's life.

The patient, a lorry driver, aged 23, suffered from bronchiectasis following a post-operative bronchopneumonia two years ago. He was expectorating about a pint of fetid sputum daily, and had lost 3 st. in weight. On admission on 15th August, 1932, he weighed 7 st. 5 lb. There was marked clubbing of the fingers, and the physical signs suggested a gross bronchiectasis at the base of the right lung, with some involvement also of the left base, though to a less degree. These findings were confirmed by x-ray examination after intratracheal lipiodol. He was treated by inhalations of creosote, by postural drainage, and by bronchoscopic lavage; but his condition slowly and steadily deteriorated. On 16th January, 1933, phrenic avulsion was attempted under local anaesthesia, the operating table being tilted up so as to elevate the head and chest. The nerve was exposed in the neck and clamped, whereon the patient hiccuped once, and immediately became acutely dyspnoeic. After an abortive attempt to cough he lost consciousness. A tracheal catheter was passed at once and a considerable quantity of pus was aspirated. Oxygen was then blown in via the trachea, and the patient's condition slowly improved. The skin incision was rapidly closed, no attempt being made to proceed further with the operation. The patient was sent back to the ward, where he again became acutely dyspnoeic, and died before further aid could be given. At the necropsy there was found complete collapse of the lower half of the right lung. The trachea and the main bronchi contained much pus. There was gross bronchiectasis, involving the right lower lobe, with cavities the size of a walnut. There was a much less marked degree of bronchiectasis involving the rest of both lungs. Death was evidently due to asphyxia consequent on the sudden flooding of the whole bronchial tree by pus squeezed out of the bronchiectatic cavities in the right base when the right dome of the diaphragm made its rapid ascent.

The Cost of an Adequate Diet

(Abstracted from the *Lancet*, 25th November, 1933, p. 1215)

It has not been possible in the circumstances to reconsider the fundamental principles on which nutritional needs are generally estimated, and it is open to bold critics to say that these principles are unsound. If the classical physiological observations stand, however, the rest of the Committee's findings must be accepted in substance. They are based on an assumption that the adult male requires on the average 3,400 calories a day to keep body and soul in good working order; and this, it is true, exceeds most previous estimates by 400. On the other hand the report offers good reasons for the increase, and in practice the extra amount is made up from cheap carbohydrates which add little to the cost of the diet. In calculating the proportionate requirements of women and children the Committee adopts the scale laid down by E. P. Cathcart and A. M. T. Murray which enables one to express a family's needs in 'man-values'; for example, a husband, wife, and four children have the same calorie needs as 4.63 adult men. Calories, however, are not enough, even when seasoned with vitamins and minerals, and the Committee draws its conclusions from specimen diets which could in fact be tolerated by the consumers and have the necessary flavour of variety. Again, for children it rightly insists on a disproportionate supply of first-class protein and bases its estimates on an item of one pint of milk per day for every child from one to six years of age.

The specimen diets have been prepared as economically as possible, and the approximate cost of each is given. Prices, however, vary from time to time and place to place, and the Committee names no one sum that may be supposed to cover the weekly needs of the adult male. Instead it offers two scales of cost—one based on the prices ruling in a single locality (Stockton-on-Tees) during twelve months, and one (the B. M. A. scale) based on the prices current in a number of areas throughout the country during two weeks of last summer. The Stockton scale is the lower because Stockton—hard hit by the depression—is a very cheap market; but the difference is more apparent than real, since it is mainly accounted for by the purchase of flour instead of bakers' bread. In Northern towns the bread is made at home and the cost is thereby reduced; it should be noted, however, that the Stockton figures make no allowance for fuel. The following table gives the 'family coefficients':—

		COST PER HEAD PER WEEK (TO NEAREST 1d.)	
		Man-value calorie Coefficients.	B. M. A. Stockton scale scale
			s. d. s. d.
Adult male ..	1.00	5 11	5 0
Boy over 14 years ..	1.00	5 11	5 0
Adult female ..	0.83	4 11	4 2
Girl over 14 years ..	0.83	4 11	4 2
Child 12 and under 14 years	0.90	5 4	4 6
" 10 " 12 "	0.80	4 9	4 0
" 8 " 10 "	0.70	4 2	3 7
" 6 " 8 "	0.60	3 7	3 0
" 3 " 6 "	0.50	3 5	3 0
" 2 " 3 "	0.40	3 1	2 10
" 1 " 2 "	0.30	2 8	2 6

This table which really contains the main conclusions of the report, gives both scales, and it will be seen that the Committee holds that the lowest expenditure which will support both health and working capacity in the adult male is 5s. a week in Stockton and 5s. 11d. in the other areas studied. This is in line with previous

estimates, but the Table brings out even more emphatically the large needs of children. It has proved impossible even at Stockton prices to devise an adequate diet for a child at less than 2s. 6d. a week and the cost rises rapidly with age until the boy of fourteen reaches the adult level.

(Note.—The figures given in the report of the British Medical Association Committee on Nutrition are naturally not applicable in India; nevertheless we feel that this short summary, taken from an editorial note in the *Lancet*, will be of interest to our readers, even if only for purposes of comparison.—Editor, *I. M. G.*)

The Modern Treatment of Pyorrhœa

By A. T. PITTS, D.S.O., M.R.C.S., L.R.C.P., L.D.S.

(Abstracted from the *Medical Press and Circular*, 20th December, 1933, p. 558)

The term 'pyorrhœa alveolaris' in a broad sense may be taken to mean a chronic general infection of the supporting tissues of the teeth, leading to their eventual destruction. The implication in the term that a discharge of pus from the gum margins is the most important feature of the disease is of doubtful truth. At some stage in most cases there is a discharge of pus, but it is not invariable, nor is it necessarily the most significant feature. Perhaps the following definition might command a fairly general, though not unanimous approval: 'Chronic general periodontitis (pyorrhœa alveolaris) is a disease characterized by a progressive inflammation and ulceration commencing at the gum margin and invading the periodontal membrane. Concurrently with the destruction of the periodontal membrane there is a rarefaction of the alveolar bone. As the supporting tissues of the teeth become destroyed the teeth become gradually looser. At some stage of the disease there is usually, though not invariably, a discharge of pus from the pockets formed by the destruction of the periodontal membrane. Secondary changes of a necrotic or regressive character affect the cementum, dentine and pulp. In some cases the bone changes are of a progressive, rarefactive character throughout, but in other cases rarefaction may be replaced by sclerosis or production of bone with fibrosis of the gum, so that the teeth remain firmly implanted until a relatively late stage'. Such a definition describes the common sequence of the clinical features. One point of clinical interest emerges, which is that two main types of pyorrhœa can be recognized. In one the pockets are deep, and the progress of the disease is rapid. There is a good deal of tartar on the teeth. The gums are hyperæmic and dark in colour. They bleed readily, and are often tender. The patients are often young adults with narrow, slender jaws. There is often a history of nasal obstruction and mouth-breathing. In this type we may say that there is little sign of tissue resistance to the infection, and general symptoms of toxæmia are not infrequently present. In the second type there is a fibrosis of the gums which proceeds concurrently with the bone destruction, so that deep pockets are not formed. The gums may be normal in colour and free from tenderness. There is not much tartar present. The relative absence of pockets means that food and bacterial stagnation do not occur. The jaws are large, and the dental arches well found. The patients have a vigorous habit of chewing, and there is usually a good deal of wear of the teeth. Such patients may be in excellent health, with an entire absence of any general symptoms which could be referred to the oral condition. But in the end, though this may be long delayed, the bone destruction will outstrip the fibrosis of the gums, and pockets will be formed which permit of stagnation of food debris and bacteria. It is permissible to regard the fibrosis of the gums and sclerosis of bone as signs of tissue resistance. Clinically, the prognosis is good, and little treatment is required.

It is impossible to discuss the treatment of pyorrhea without some reference to its etiology. Much confusion exists, and theories abound, all of which have some plausibility, but lack convincing proof. Some authorities hold strongly that pyorrhea is local in origin. There is much to be said for this point of view. Yet it overlooks certain aspects which certainly suggest some general factor. All conditions which favour food stagnation undoubtedly predispose to pyorrhea. Thus, mouth-breathing, irregularities of the teeth, dietetic factors, spacing due to loss of teeth, defective fillings or crowns, and ill-fitting dentures—all of these may favour the onset of the disease. Yet it occurs in patients in whom none of these factors are present, while, conversely, local conditions unfavourable to oral hygiene may be compatible with a good condition of the gums. Other authorities would find the explanation in some general metabolic disturbance, which, co-operating with some local condition, determines the onset of pyorrhea. The views of F. W. Broderick have attracted considerable interest. He believes that the disease is primarily due to endocrine disturbance, which upsets the balance of calcium metabolism in the direction of lime saturation, and brings about a chronic alkalosis. This increases the calcium content of the saliva, and causes a diminution of the CO_2 content of the blood, leading to a deposition of calculus around the necks of the teeth, which in its turn is the actual exciting cause of the gingival lesions.

It is not possible to discuss further this vexed question in the limits of this article, but enough has been said to make it clear that the treatment of pyorrhea is to some extent empirical and directed to the amelioration of symptoms rather than a rational attack based on a proven etiology.

TREATMENT

It must be premised that cure in the sense of a restoration to the normal is not yet possible. Since the essential lesion is a destruction of bone and periodontal membrane, a restoration to the normal would imply a reformation of bone and a re-attachment of the periodontal membrane. There is no evidence that this is possible. This is not to say that with a more accurate knowledge of etiology and pathology a method of treatment may not be devised which will make such a complete cure possible; but at the present time we know of no treatment which can accomplish such a regeneration of tissue. It is true that a gingivitis in which the supporting tissues are not affected may be completely curable without permanent loss of tissues. Since many writers hold that pyorrhea starts as a gingivitis, in this sense it might be said that a restoration to the normal might occur. But the writer has always felt that this was an unfair attitude. Assuming that in every case of pyorrhea there has been an antecedent and initial gingivitis, yet the converse does not hold good that every case of gingivitis is the prelude to pyorrhea, for many cases of gingivitis occur which do not lead to pyorrhea. It is easy to claim to cure pyorrhea in this restricted sense, but it is essentially a deception, and in contrast with more modest claims suggests the possession of some form of therapy not generally known. But the writer must hasten to say that such claims usually proceed from loose thinking rather than from any deliberate intention to deceive.

In the present light of our knowledge the word 'cure' as applied to the treatment of pyorrhea means a stabilization, as permanent as possible, of the destruction of the supporting tissues of the teeth at the level they have arrived at when treatment commences. The disease may be arrested therefore, and since the term 'cured' is often used in this sense, it is legitimate to apply it to the treatment of pyorrhea, provided that its limitations be clearly understood.

There is a vast and ever-increasing literature devoted to the treatment of pyorrhea which reveals more clearly than anything else the inadequacies of our

knowledge. It is a sound principle to examine all methods of treatment of a disease in the light of general principles. When so examined it will be found that many new forms of treatment, for all their apparent novelty, are only fresh expressions of old principles.

The various methods of treating pyorrhea can be grouped under such headings as mechanical, surgical, medicinal, electro-therapeutic and immunological. It is safe to say that all the many methods which have been advocated fall under one or other of these headings. A simpler grouping would be those which destroy infection and those which promote drainage. A still further division of great importance is treatment carried out by the dentist and that carried out by the patient. Each is complementary to the other, and the absence of co-operation by the patient is fatal to success. It should also be emphasized that no one method is likely to be successful alone; it is the combination of various methods which is all-important.

MECHANICAL TREATMENT

The first thing which should be done in every case of pyorrhea is to scale the teeth thoroughly. It is essential to remove all tartar from the teeth, especially those particles which adhere to the roots, and are thus below the gum margins. If this be not done, all other treatment is a waste of time and money. This is far from easy and may necessitate several visits. A mere hasty removal of the obvious masses of tartar followed by a polishing of the teeth is useless. To be effective it must be a carefully planned procedure which demands patience and a delicate tactile sense.

MASSAGE OF THE GUMS

Following the scaling of the teeth, a course of massage of the gums should always be instituted. Rubber vibrators which can be used in the dental engine have been devised, but in the writer's view massage is essentially a form of treatment to be carried out regularly by the patient. A useful adjuvant is glycerine and tannic acid. The procedure is to wrap a piece of muslin round the finger and dip it in the glycerine and tannic acid. The gums should be vigorously rubbed both transversely and vertically, and on both surfaces. This should be done for a few minutes twice a day. A period of about three weeks is sufficient for the use of glycerine and tannic acid. It may then be replaced by a solution of salt and water, a teaspoonful of salt to a tumbler of water. This should form a permanent part of the hygiene of the mouth as practised by the patient. Massage acts by inducing a circulation of blood in the tissues, and promotes fibrosis of the gums. It is surprising how quickly it brings about an improvement. In two or three weeks it is quite common to find that the tenderness and tendency to bleed readily have disappeared; the gums lose their dark congested appearance, while their shrinkage is shown frequently by the presence of fragments of tartar deeply placed, which have become exposed like rocks by a receding tide.

TREATMENT BY DRUGS

The local action of drugs depends on their action as caustics, disinfectants, or astringents. Innumerable drugs have been advocated, and good results have been claimed for all of them. There is nothing to suggest that any drug has a specific action. Creosote and alcohol in equal parts and chromic acid may be taken as representative of caustics. Their usefulness, however, is evanescent. So long as pockets remain, stagnation must occur. Still, they have a place in the treatment of pyorrhea.

The disinfectants are even more numerous. Hydrogen peroxide acts as a mechanical agent, through the bubbles of oxygen removing debris, rather than as a disinfectant. Its use, however, is considerable. Most dentists have compressed air laid on in their surgeries, and it is a useful procedure to spray round the mouth and flush out the pockets with peroxide on each visit.

Iodine, mercurochrome and lysol are a few disinfectants which may be mentioned. Since spirochaetes in combination with the fusiform bacillus are often present in the pockets, the use of a preparation containing arsenic has been advocated by Kritechevsky and Séguin. But evidence that these organisms in symbiosis are the cause of pyorrhœa is lacking. While liquor arsenicalis may be useful, there is nothing to show that it acts as a specific. Ipecacuanha, or its active principle, emetine, has also been employed on the assumption that the *Endamæba buccalis*, which is often present, is ætiologically significant. Here, again, there is nothing to show that this is so. Specific therapy, therefore, does not exist, in spite of extravagant claims which are sometimes made for various remedies. Astringent drugs like copper sulphate and zinc chloride are useful in the early stage in order to promote shrinkage of the inflamed gums.

MOUTH-WASHES

It is perhaps not an exaggeration to say that the most important ingredient in most mouth-washes is the water. Their main purpose is to flush out the mouth and to remove debris. Claims that this or that drug will destroy bacteria found in the mouth may be true of experiments *in vitro*, but it is a fallacy to imagine that any antiseptic can be used in the mouth of such a strength that it will reduce the bacterial flora to any appreciable degree. Experiments which have been carried out show that any reduction is temporary, and quickly made up. When it is remembered that in pyorrhœa there are irregular pockets round the teeth lined with infected tissue, it will be obvious that the antiseptics used in a mouth-wash can only play a minor part in the treatment of pyorrhœa. But few patients will believe this; so that if only to inspire confidence, a mouth-wash containing some antiseptic is a useful measure. Astringent mouth-washes are useful however. A pleasant and effective example is Lavis, a Canadian preparation. Hydrogen peroxide (five vols.) is useful, as the mechanical flushing action is increased by the effervescence of the nascent oxygen. An ingenious apparatus called the Hygienator has recently been put on the market which embodies the principle of the 'Sparklet' syphon. A suitable solution containing CO₂ under pressure, to which hydrogen peroxide can be added, can easily be made up, and the fluid can be sprayed round the mouth under considerable pressure.

SURGICAL TREATMENT

Since all tissue above the level where bone and periodontal membrane is still intact adds nothing to the stability of the teeth, and merely allows stagnation, it would seem a rational procedure to excise this tissue and thus obliterate the pockets. For many years this has been a common procedure, giving excellent results. It should only be done after preliminary treatment to reduce inflammation, and to get the tissue into as healthy a condition as possible. The operation can be performed under a local anæsthetic. Small and very sharp scalpels must be used, and various useful types have been devised. Recently H. Stones has advocated gingivectomy on a more extensive scale. He excises a strip of tissue on both labial and lingual aspects, down to the level of the bone round all the teeth affected. This is a lengthy procedure, which according to Stones may take over an hour to perform. It can be done under a local anæsthetic, but obviously is much more severe than the excision of the pockets of a few teeth at a time, chiefly in the incisor and canine region. Good results are claimed for this treatment, which has the merit of being based on a sound pathology. But it must be emphasized that it does not replace other methods, such as massage and scaling, nor is it applicable to every type of case. Some operators prefer the cautery to the scalpel. Even more elaborate methods have been advocated in America, involving reflection of the gum and curettage of the

bone, but the writer remains sceptical of their advantage over methods less pretentious and severe.

GENERAL TREATMENT

It is highly probable that in many cases of pyorrhœa there are general factors of importance. But too little is known to enable us to use a therapy of a general character with much certainty. It has been argued that the local condition may be secondary to intestinal stasis, and that treatment devoted to the intestinal condition, such as the regular use of liquid paraffin, would be beneficial. Gottlieb recommends the use of Fowler's solution internally, commencing with five drops once daily for five days, and gradually working up by successive increases of five drops every five days up to thirty drops daily. The dose is then diminished gradually to five drops again. He believes that arsenic stimulates the growth of bone. F. W. Broderick, whose views have attracted much attention, believes that pyorrhœa is essentially a local reaction to a condition of alkalosis. He advocates the use internally of ammonium chloride. About two grains should be taken before breakfast. After a few days the reaction of the saliva should be tested, and the dose increased or diminished until normal salivary pH is reached.

ELECTRO-THERAPY

The action of drugs may be increased by ionic medication. Those who practice this method are enthusiastic in their belief in its value. It is claimed that a deeper penetration of the drug into the infected tissue of the pockets can be obtained by ionization. Such drugs as zinc chloride, tincture of iodine and eucal can be used. A few teeth should be treated at a time with a current ranging from one to four milliamperes. The electrode should be held in contact in one spot from one to three minutes.

VACCINE THERAPY

Many organisms are found in pyorrhœa pockets, but none of them fulfil the necessary criteria to be regarded as the specific cause. From this point of view vaccine therapy is empirical. Since, however, the streptococci present are in all probability the organisms responsible for the general symptoms which may be caused by a focal infection in the mouth, a vaccine may sometimes benefit the general health. But whether vaccines do any good locally is another matter. The general opinion at the present time is that vaccine therapy has little if any value in the local treatment of pyorrhœa.

THE EXTRACTION OF TEETH

No account of the treatment of pyorrhœa, however brief, would be complete without some reference to the extraction of teeth as part of the treatment. Space does not permit of a discussion of the points which will influence the decision to extract the teeth, or to treat the disease by conservative methods. But given the decision that conservative treatment is permissible, there is still a place for partial extraction as part of the treatment. Thus the removal of certain teeth so as to create spaces, will remove the stagnation areas and enable the remaining teeth to be kept clean without much difficulty. No rules can be laid down, for the decision as to whether the extraction of any teeth will improve the hygiene of the mouth must depend on the amount of bone destruction as evidenced by clinical examination and radiographs of the teeth.

TREATMENT BY THE PATIENT

The part played by the patient is of the utmost importance. Unless there is a whole-hearted co-operation by the patient, the best efforts of the dentist will only produce a transient improvement. A careful and regular ritual of oral hygiene must be practised. Cleaning the teeth, massage of the gums, the use of silk or wool to remove debris from round the teeth, the flushing out of the mouth with a mouth-wash, are all essential. Here is the real difficulty in the treatment

of pyorrhœa. So many patients mean well; they start off with enthusiasm, which soon wanes week by week, until a rationally planned ritual degenerates into a perfunctory toilet of the mouth. Their condition lapses until the next visit to the dentist awakens a fresh spurt of enthusiasm. But each time the improvement tends to be on a lower plane, until eventually the disease reaches a stage which makes extraction inevitable. There is perhaps no disease in which it is easier to bring about some improvement; but there are few diseases in which it is harder to maintain the improvement over any length of time.

The cry of the patient, like Naaman, the Syrian, is always for the waters of the Abanah or Pharpar, which will bring some miraculous cure. But the humbler methods, based on time-honoured principles of pathology, though less showy, still remain the sheet anchor in our treatment of pyorrhœa. Used intelligently and carefully by both dentist and patient, they will not accomplish miracles, but they will arrest the progress of the disease in a considerable proportion of cases.

Artificial Pneumothorax Treatment

By G. JESSEL, M.D. (Oxf.), D.P.H. (Manch.)

(Abstracted from the *Lancet*, 16th December, 1933, p. 1360)

ARTIFICIAL PNEUMOTHORAX has been steadily growing in popularity during the past few years, but it is still employed sparingly by some workers. Fishberg, with his vast experience in America, considers that hardly 5 per cent of tuberculous patients can be regarded as suitable for the treatment, while Henf has recently drawn attention to the misuse of artificial pneumothorax both clinically and administratively. Many favourable statistics have, indeed, been published, but it is difficult to obtain absolute proof by such means. In fact, it has been suggested by Shaw that an experience of statistical dimensions actually treated is practically impossible. One difficulty is that medical superintendents of institutions are seldom responsible for the treatment of patients on discharge, and often find it difficult to follow up their cases.

Artificial pneumothorax—the greatest advance in treatment since the inception of the sanatorium—is, in fact, a particular application of the fundamental principle of sanatorium treatment, *viz.* rest. By compression of the lung, through the introduction of air into the pleural cavity, local rest of the affected part is obtainable. In practice the possibilities of applying the treatment are limited. Severe bilateral cases have usually to be excluded, and in patients with less extensive disease the introduction of air is frequently impossible owing to adhesion of the diseased lung to the chest wall. The success of the treatment in certain acute forms of unilateral disease is often marked, but many types of case are unsuitable, and the majority of experienced workers agree that artificial pneumothorax should not be lightly undertaken. Apart from the duration of treatment (refills necessary at intervals for about three years), each individual patient requires special consideration, not only as regards suitability but subsequently before each refill.

SELECTION OF CASES

Recent unilateral cases with comparatively slight involvement of the opposite lung are particularly suitable, especially in young subjects. Some of the most dramatic results are seen in such patients. High fever disappears, sputum is lessened, and the condition steadily improves. Good results are also frequently obtainable in patients with more extensive lesions, dependent upon the amount of fibrosis and the closure of cavities, if present. On the other hand, patients with much fibrosis, and particularly those of middle age, should not be given artificial pneumothorax as they are apt to be made worse by it. The point as to how

long it is desirable to wait before induction is debatable. If a patient is doing well with bed-rest there is no advantage in initiating a form of treatment which, owing to its duration and possible complications, may prove troublesome.

There is an impressive weight of opinion in favour of a preliminary period of conservative or sanatorium treatment. Others, however, consider that the percentage of real recoveries would be increased if all cases with tubercle bacilli in the sputum and definite signs of unilateral disease had artificial pneumothorax induced at once, instead of waiting to watch the results of an actual period of simple medical treatment. My patients are invariably requested, as soon as tuberculosis is diagnosed, to remain in bed at home until their turn for admission to the hospital arrives, so that it is usually possible to reach a decision as to their suitability for artificial pneumothorax treatment soon after they are admitted, as a comparison can be made between the clinical and radiological evidence obtained on diagnosis and on admission after a period of bed-rest.

In the majority of cases bacilli were found during the course of the illness. Since the utilization of good skiagrams has, in combination with clinical evidence, placed diagnosis on a more satisfactory basis than obtained in pre-radiology days, it is not my practice to wait until bacilli are demonstrated in the sputum, as valuable time may thereby be lost. In fact, as will be shown later, the percentage of negative sputum cases alive after a given time was found to be twice as high in those who received artificial pneumothorax as in those where this was unsuccessful or abandoned.

It is convenient to subdivide possible cases of pneumothorax into classes representing degrees of suitability for this form of treatment. In this connection it is generally agreed that the extent of the disease should be considered with definite reference to the presence or absence of cavitation in the lung chosen for collapse, and the presence or absence of disease in the better lung, both founded on a combination of radiological and physical findings.

TECHNIQUE

The pneumothorax apparatus designed by Peter Edwards has been found simple, effective, and reliable. Treatment is given in bed at first, and subsequently in a special treatment-room, x-ray screening beforehand being the rule, with skiagrams at intervals. An injection of omnopon, gr. 1/6th, is given subcutaneously half an hour previously. Local injections of 2 per cent novocain with 1 : 100,000 adrenaline are given at the induction and before the first two refills, and are then discontinued. The first three refills are given at daily intervals; thereafter every other day, the period being gradually lengthened to a maximum interval of two to three weeks. At first, 300 c.cm. of air are given, and this may be increased to 500 to 600 c.cm. Small and frequent refills are preferred, as the result is more likely to be collapse of the diseased portions only (selective collapse) while, in addition, effusions tend to occur much less frequently than have been reported when big refills at long intervals (6 to 8 weeks) were in vogue. In my series effusions, requiring gas-replacement on one or more occasions, occurred in 20 cases.

Artificial pneumothorax is often advantageously combined with other forms of treatment and is, of course, superadded to the sanatorium regime of the hospital. In agreement with the experience of Burrell and others, sanocrysin has been found of benefit in some cases, where the disease has spread to the opposite lung, and the phrenicectomies performed by Mr. Morriston Davies on over 50 of my cases have also been found useful where the degree of collapse was slight or inadequate. (The word phrenicectomy is used to include cases where phrenic evulsion was done. The latter operation, which aims at a gradual evulsion of the whole of the nerve, has been latterly modified by Mr. Davies. He now removes a segment of the nerve

and divides such accessory phrenic nerves as can be found—phrenicectomy.) This operation avoids the risk of pain, injury to lung, or hæmorrhage, which may occasionally follow evulsion.

DISCUSSION

Artificial pneumothorax was attempted in 139 out of 487 admissions of definite cases of pulmonary tuberculosis—i.e., 28 per cent. A satisfactory collapse was obtained in 59 out of 99 T.B.-plus cases, and in 26 out of 40 T.B.-minus cases—i.e., in 17 per cent of the total cases admitted. The tables show that, of patients so treated, a considerable number of men were working or fit, and had lost their bacilli at the end of 1932. This disappearance of bacilli has a distinct bearing on public health, because thereby important sources of infection are removed. There is reason to believe that in my dispensary area more T.B.-plus cases are alive, relatively to the total number of tuberculous patients, than before the introduction of collapse therapy, and the impression that such patients live longer is thus strengthened. Their regular attendance at the dispensary for refills is noteworthy, and by their obvious improvement in health they help to raise the morale of their fellow-patients, both in hospital and as out-patients. This in itself is significant. The results in the T.B.-plus cases of artificial pneumothorax satisfactorily applied and in cases with fibrosis where this was impossible (but where in 19 out of 31 phrenicectomy was done) show a striking similarity.

It thus appears that we must regard artificial pneumothorax as but one aspect of collapse therapy, which includes phrenicectomy and, occasionally, thoracoplasty.

SUMMARY

(1) Artificial pneumothorax is a valuable adjunct to treatment in an appreciable, but limited, number of patients. It assists restoration to working capacity and leads to the disappearance of bacilli from sputum in a great many cases.

(2) The benefits of this treatment are thus not limited to the patient, but have an important bearing on prevention.

(3) Artificial pneumothorax is a form of collapse therapy and must be considered in relation to other forms. In cases unsuitable for this treatment good results are often obtainable from phrenicectomy.

(4) The favourable impression that patients undergoing collapse therapy create on the minds of their fellow-patients, both in hospital and at dispensaries, is an indirect testimony to the value of the treatment and incidentally is important as affecting the morale of the other patients.

(5) The results of collapse therapy suitably applied are often appreciably better in a given time than the results of treatment used to be without it, although the close supervision that is needed in connection with artificial pneumothorax must be given due weight in assessing the value of this special ancillary method of treatment.

Reviews

RECENT ADVANCES IN MEDICINE: CLINICAL LABORATORY THERAPEUTIC.—By G. E. Beaumont, M.A., D.M. (Oxon.), F.R.C.P., D.P.H. (Lond.), and E. C. Dodds, M.V.O., D.Sc., Ph.D., M.D., F.R.C.P. Seventh Edition, 1934. J. and A. Churchill, London. Pp. xvii plus 485, with 58 illustrations. Price, 12s. 6d.

If one is to accept the title of this book without comment, one must conclude that during recent years few advances in medicine have been made outside the laboratory, as it would be no exaggeration to say that 90 per cent of the book is devoted to laboratory methods, though admittedly the clinical application of the observations made thereby are never lost sight of. Another point that should perhaps be made clear, in view of the fact that this is the seventh edition of a book that was first published ten years ago, is that it does not confine itself to additions that have been made to our knowledge since the last edition was published, but includes advances that were 'recent' ten years ago when the book was first published. The subject is, however, brought completely up to date, and a number of additions and a few deletions have been made; the former amount to 100 pages and seven new figures.

Matter has been added regarding sex hormones, the vitamins, calcium metabolism, nephritis, diabetes, and anæmia, to name only a few of the subjects. A number of chapters have been re-written, and sections have been added on ketogenic treatment, uroselectan pyelography, the electro-cardiographic changes in coronary thrombosis, respiratory efficiency tests, the treatment with sancrysin, agranulocytosis and its treatment, and many other subjects.

It is a book of undoubted value to the specialist and the medical man working in a town. It will also help the country practitioner to keep in touch with modern advances and to show him the direction in which modern medicine is tending, but we doubt if it will be of much *practical* value to the latter class of reader. Take, for example, the colorimetric estimation of

hæmoglobin in the chapter on blood and urinary analysis; the method described necessitates the use of a Newcomer type of colorimeter which costs about two hundred rupees, so that to the practitioner with nothing but a faded Tallqvist scale this section will not give much help.

The book is quite up to the standard of its predecessors, and of this excellent series of publications.

L. E. N.

RECENT ADVANCES IN VACCINE AND SERUM THERAPY.—By Alexander Fleming, F.R.C.S. (Eng.), and G. F. Petrie, M.D. (Aberd.), 1934. J. and A. Churchill, London. Pp. x plus 464, with 5 illustrations. Price, 15s.

AFTER a very careful perusal of this book we have no hesitation in saying that this is one of the most important additions to the Recent Advances Series. The book is divided into two parts; part I, which deals with the prevention and treatment of diseases by means of sera and with the specific prophylaxis and treatment of virus diseases of man and animals, has been written by Dr. Petrie; part II, which gives an account of the prevention and treatment of diseases by means of vaccines, is by Professor Fleming. The authors have undertaken a careful survey of the present state of knowledge regarding the employment of vaccines and sera in the prevention and treatment of disease. In each section after a short reference to the methods of preparation of vaccines or sera the various problems connected with each particular disease are discussed briefly but lucidly. The prophylactic and therapeutic employment of vaccines and sera, their dosage and value are fully detailed. The gaps in our knowledge, where they exist, and ideal schemes of clinical investigations are fully discussed. The whole book has been so written that it will appeal both to the specialist and to the practitioner. The charge has often been made that the practitioner of to-day approaches the patient armed with a syringe and needle instead of the

stethoscope and it must be admitted that there is a great deal of justification for such a charge. There has been a growing tendency towards the indiscriminate use of vaccines and sera. The realization that the efficacy of vaccine preparations depends upon their antigenic components and the importance of bacterial variations in immunology, and that sera owe their therapeutic activity to the antibodies that they contain, will go far to put vaccine and serum therapy on a firmer, sounder and scientific basis. The book should be read by all practitioners of medicine, whether they are or are not convinced of the value of vaccine and serum therapy. To both a recent summary of the whole subject will prove of value and to those who desire further information a useful bibliography is given at the end of each chapter. The book is well written and the printing and general get-up are excellent.

C. L. P.

THE RADIOLOGY OF BONES AND JOINTS.—By James F. Braltsford, M.D. (B'ham), M.R.C.S. (Eng.). 1934. J. and A. Churchill, London. Pp. xx plus 500, with 310 illustrations. Price, 30s.

THE author of this book, well known to radiologists from his numerous contributions to current literature, is Radiological Demonstrator in Living Anatomy at the University of Birmingham. The fruits of combining radiology with instruction in anatomy are partially manifest in this excellent volume. It is a pity that more universities do not follow the example of Birmingham in this respect.

The book contains an enormous amount of information both on the normal skeleton including non-pathological variations and on the changes due to disease. Where the information appears to be restricted direct reference to the source of the information will always be found. The text and illustrations indicate that the work is based on vast personal experience and a bibliography of eighteen pages, arranged at the end of the book in a really practical manner, suggests a wealth of reading by the author and makes the book exceptionally up to date and authoritative. The radiographic reproductions are in all cases in the positive and are as fine as any the reviewer has seen in medical textbooks. Almost without exception they convey what is intended by the author in the text and where necessary line drawings are liberally used. The specimens given of some of the rarer diseases, such as Schmorl's nodes, vertebral angioma, Albers Schonberg's disease, are of the type likely to help a man who has not met with them before.

The book should prove a mine of information to the keen clinician and must for long remain an indispensable volume of reference in any radiological department. It is produced by the house of J. and A. Churchill and is another sound addition to their long list of successes.

H. R. R.

THE CHANCES OF MORBID INHERITANCE.—By Various Authors. Edited by C. P. Blacker, M.C., M.A., M.D., M.R.C.P. 1934. H. K. Lewis and Co., Ltd., London. Pp. xii plus 450. Illustrated. Price, 15s.

In expressing an opinion on this book, we find it extremely difficult to avoid a certain literary cliché, very dear to the amiable reviewer. It is the type of book which one opens thinking that one is treating oneself to a little luxury reading, and puts down with a feeling of wonderment that the general practitioner has been able to face the cross-questioning of his patients for so long without the precise knowledge on the subject of heredity and disease with which the reading of this book will equip him. It may be said that the information was available—somewhere. But it was certainly not to be found in the general run of medical literature, or anywhere, in this concise form.

Few titles of books are more completely self-explanatory, but, if any further explanation as to the scope of this book is necessary, this is provided in the first paragraph of the preface—'Its object is to supply to the general practitioner the means of dealing with a request for a eugenic prognosis'. The editor claims that space has been allotted to the various subjects in proportion as the practitioner is likely to be asked about them, rather than in proportion to the sum of our knowledge thereon; this in our opinion is not quite the case. We should have thought that the inheritance of cancer was one of the commonest subjects of popular enquiry, but the information given is particularly meagre. This is perhaps because knowledge on the subject is very limited; nevertheless, we found it the only disappointing chapter in the book. On the contrary mental deficiency, which has quite rightly been given a chapter to itself, and a long one, and which is probably one of the most important subjects from a racial point of view, does not, we should imagine, often form the subject of questioning for the general practitioner, though it is a matter of primary concern of the public health officer and the medical inspector of schools.

It is difficult to pick out any chapter for special mention, but the first chapter, on genetic principles, is probably the most important. We have not hitherto read an exposition of the modern views on Mendelian inheritance that has been so easy to follow. This chapter will form a valuable introduction to the study of genetic principles, not only for the general practitioner but for the student who proposes to make a special study of this subject.

The writer on the subject of heredity and tuberculosis seemed to the reviewer to make a mistake in taking up a defensive attitude. He suggested that ever since the discovery by Koch of the causative organism of this disease, too much attention has been paid to the bacterial aspect of the problem, and that the medical profession had tended metaphorically to spell 'tubercle bacillus' with a big 'B'. (We assume that it was countervailing influence that this writer chose to spell Tubercle with a capital 'T' throughout the chapter; but why did he write 'tubercular infection' when he meant 'tuberculous'?) The extreme expressions of opinion that he quotes are not typical of the general medical opinion to-day, nor did the pendulum ever swing so completely from the 'tuberculous' diathesis of our grandfathers as he pretends to believe. If emphasis has been laid on environment, it has been because it was more likely to produce results than emphasis on heredity. It is not much use telling tuberculous parents that they should not have had a large family, but it is often possible to get the latter away from their infectious surroundings. The case for differences in herd susceptibility is surely fairly generally accepted, and the writer did not seem to be able to make out any case for the inheritance of individual hyper-susceptibility. Nevertheless, this chapter was an interesting one.

The inclusion of a glossary of genetic and psychiatric terms was a good idea, but this might have been fuller with advantage. The pedigree schedule, devised by the Eugenics Society, which can also be obtained separately, should prove a valuable help to the medical man and relieve him of a good deal of personal investigation when a patient asks for a eugenic prognosis.

As we have said above, this book is an important addition to the practitioners' library; the social worker will also find it invaluable.

L. E. N.

METABOLIC DISEASES AND THEIR TREATMENT.—By Dr. Erich Grafe. Translated by M. G. Bolso. 1934. Published by Henry Kimpton, London. Pp. 551. Illustrated. Price, 32s.

THERE appears to be little doubt that the subject of the diseases of metabolism occupies an important position in the field of internal medicine of the present

day and it is pleasing to remember that continued and increasing attention is being directed by the medical profession towards the solution of this important subject. The keen interest which is manifested by research workers all over the world in trying to work out some of the difficult and intricate problems in certain nutritional disorders, and in such metabolic diseases as obesity, diabetes, etc., is really commendable. This has certainly helped to throw light on many of the hitherto-unexplored problems, helping towards a much better understanding of the subject as a whole.

This book originally appeared in the German language about two years ago, and the present volume, which has been completed since then and brought up to date, has been translated into English under the supervisions of people who may be considered authorities on the subject.

The book is divided into five parts with an appendix at the end. The first part is concerned with general discussions regarding metabolism and nutrition; part II deals with anomalies of nutrition and their dietetic treatment; in part III (which covers more than half of the book), the author has dealt with the two of the most important diseases of metabolism, namely obesity and diabetes, in an admirable manner. Its perusal will amply repay the reader for the time given to it. Part IV deals with diseases due to disturbance of protein metabolism, such as gout and cystinuria, and the last part of the book deals with disturbances of the water and mineral economy and includes diabetes insipidus. In the appendix, the author has dealt with the diseased conditions of general interest, such as calcareous diatheses, oxaluria, and phosphaturia.

We welcome this book not only because it is one of the few books which deal with these subjects in a clear, concise and precise form, but also because the book deals specifically with all the metabolic diseases in a way that is most useful both to the doctors and the students.

J. P. B.

A MANUAL OF DISEASES OF THE NOSE, THROAT AND EAR.—By E. B. Gleason, M.A., LL.D. (Lond.). Seventh Edition. 1933. W. B. Saunders Company, Philadelphia and London. Pp. 651. Illustrated. Price, 21s.

THIS is the seventh edition of this very useful manual. It has been revised and entirely reset.

So far as I know there is no book of its size in the English language which deals with all three subjects, i.e., ear, nose, and throat, so adequately.

The first fifty pages deal with the art of laryngoscopy, otoscopy and rhinoscopy. The descriptions are lucid and practical. There is a short description of some very useful accessory instruments such as Allen's probes, various atomizers and powder blowers, syringes, etc.

A short chapter on sterilization of instruments. And finally some hints as to examining patients and an easy schema for recording the results.

The rest of the book is divided into five sections, nose, pharynx, larynx, ear, and formulas.

Each section begins with a description of the anatomy of the part and the illustrations which accompany the text are taken from actual dissections made by Professor Gleason himself. They are all valuable and well reproduced.

The chapter on suppuration of the para-nasal sinuses has been very carefully dealt with. The author is strongly in favour of the more conservative methods which is also the modern trend in Great Britain and Europe. Nevertheless he describes the recognized radical operations on these sinuses fully, but at the same time he points out in the preface to this edition that the result is often to substitute one pathological condition for another, and that almost as much treatment is required to keep the patient comfortable as if no operation had been done. In one of the largest clinics in England they have not performed a Caldwell-Luc

operation for the last five years. A very large opening under the inferior turbinate was the operation of choice.

In the section on the pharynx the picture illustrating the line of incision for a quinsy is shown with the patient having his mouth wide open. This I suppose is necessary but the fact is not emphasized enough that in the acute stage an opening of a quarter to half an inch between upper and lower teeth is all that one gets unless a general anaesthetic is used. This to my mind is a strong argument in favour of tonsillectomy in the treatment of quinsy in the acute stage as soon as the abscess has formed. The trismus relaxes, almost at once under chloroform anaesthesia, the jaw falls open, and the rest is easy.

In the section on the larynx the operation of high tracheotomy is described. The cricoid and first rings of the trachea being cut either with a knife or scissors. The risk of stenosis of the larynx after cutting the cricoid is emphasized. I think it would have been better to have omitted the operation altogether. It is never necessary.

The fourth section of the book is devoted to the ear. It is by far the largest section. The illustrations are many and very well executed. In the opening chapter on the anatomy the author has succeeded in being brief and at the same time lucid, a combination by no means easy of attainment in this part of the body.

The fifth and last section is headed 'Formulas'. It is not a mere catalogue of prescriptions but has in addition therapeutic details and sometimes pharmacology as well, because the manner of use and the preparation of a remedy is often of more importance than the drug itself.

This section the student and the practitioner will find extremely valuable for local applications bulk so largely in the treatment of diseases of the ear, nose and throat.

The statement on page 239 that the fusiform bacillus and the spirochete of Vincent's angina are different forms of the same organism will not be generally accepted.

There are some half a dozen errors which are obviously due to the printer's devil. The other errors are I presume the American idea of how the English language should be spelt. These are only minor criticisms. The book amply fulfils its object as a manual for students and practitioners.

H. S. C.

THE ORIGIN OF CANCER.—By J. P. Lockhart-Mummery, M.A., M.B., B.C. (Cantab.), F.R.C.S. (Eng.). 1934. J. and A. Churchill, London. Pp. ix plus 150. Illustrated. Price, 10s. 6d.

THIS book is a detailed exposition of the genetic theory of the origin of cancer, sponsored by the author in 1932. It reviews the main facts and theories connected with the subject of tumours, evaluates the influence of heredity on tumour formation and explains at length the evidence in favour of the genetic theory.

Science is no longer prepared to accept the cell as a unit of life, nor the microscope as a determinant of the physical dimensions of that unit. The genetic theory of inheritance postulates genes as the ultimate units of life, the stability or mutations of which, as components of reproductive cells, determine the maintenance of fixed types or secure variations from the normal. Mr. Lockhart-Mummery visualizes the operation of a similar process in the case of somatic cells. He regards simple tumours the result of mutation of genes of rapidly dividing somatic cells, in individuals who have inherited a susceptibility for such a mutation and cancer as the result of yet another mutation in certain cells of simple tumours.

The author himself realizes that theories are always tentative and their value lies in the view afforded of a probable sequence of causes and results and the relative importance of ascertained facts.

What are the factors determining the initial and secondary gene mutations in somatic cells? The answer to this will probably come from experimental work and observations prompted by the gene theory of inheritance.

This book constitutes a notable addition to recent literature on cancer. Its style is lucid and avoids cumbersome technical phraseology so often used to lend dignity to commonplace ideas. The book is bound to interest all workers in the field of cancer research and genetics.

V. N.

THE CANCER PROBLEM AND ITS SOLUTION.—By H. Gifford, F.R.C.S. 1934. H. K. Lewis and Co., Ltd., London. Pp. II plus 60. Price, Cloth 2s. 6d.; Paper, 1s. 6d.

THIS book can be classed as being of the 'precious slender volume' type. It is, one must assume, published at the author's own expense, and in it he airs his own particular views. There is much in this book that is true, so true, in fact, and so frequently repeated that one wonders whether it was worth saying again. On the other hand there is much that, even if it cannot be called exactly untrue, is not the proven truth. Again, the book contains certain generalizations that cannot be accepted, as, for example, that 'tumours' occur in the young, cancers in the old. The nomenclature is the author's own; in this case he appears to use 'tumours' as meaning innocent neoplasms.

Reading the book as a serious contribution to science, as the reviewer did—at first, one gathers that the author's contention is that the causes of cancer can be considered as (a) exciting and (b) predisposing; the exciting causes are injury, chronic irritation, x-rays, etc.; the predisposing are embryonic 'rests' and pre-degeneration. But it is not until page 33, more than half-way through the book, is reached that the reader stumbles on the first clue to the *raison d'être* of the book; here he will find the following sentence: 'The answer to this all-embracing conundrum will appear later when we come to deal with cancer in its larger, more social aspects as a national punishment or scourge'. Even then he will have to be content with rather vague statements such as 'abundant and convincing evidence that our present degeneracy of mind and body is a source of disease', and he may feel that he has been cheated, as the reviewer did, when he is referred to another book (price 15 shillings) for more explicit details.

We must not conclude without reference to the outside of the book. The combination of black cloth, red paper and gold lettering has produced the most attractive case we have ever seen around a medical book; for this the publishers are to be congratulated.

We can recommend this book to any one with strong evangelical tendencies.

L. E. N.

RED BLOOD CELL DIAMETERS.—By Cecil Price-Jones, M.B. (Lond.). 1933. Humphrey Milford, Oxford University Press, London. Pp. 82.

SCIENCE is measurement; and therefore even since scientifically-minded man first saw in a drop of human blood the elliptical globules which we now call erythrocytes, three hundred years ago, he has wished to measure them accurately. This passion for accurate measurement of red cells is a character that has shown itself at frequent intervals in the succeeding generations of scientists during this period of three hundred years, but was repressed on account of the crudity of both the instruments and the standards of measurement that man had at his disposal, so that its presence was not evidenced by any degree of successful achievement until about 1880 when Malassez drew the first red-cell-diameter curve and gave the mean size of 100 cells as 7.7μ , after which this character seems to have been recessive in the next generation, to have appeared again, and to have achieved its maximum degree of expression

(if we may be allowed to prophesy) in the publication of the book under review.

Amongst the standards of measurement used by the early workers were grains of sand, grains of pollen, and the cross sections of human hair. In these circumstances it is surprising that some of the early attempts at measurement were sometimes so accurate; for example, Dr. James Jurin in 1718 came to the conclusion that the average size of the human red blood corpuscle was $1/3240$ th of an inch (or 7.75μ), but he spoilt this accurate achievement by making another attempt of which the result was 12.5μ (expressed in modern terms). Just over fifty years ago a writer in this journal discussed red cell measurements, and, though the method he advocated is the one in general use now, he suggested that only ten cells should be measured to obtain an average!

The author modestly describes the book as a reprint of articles on the subject of blood measurements that he has contributed to scientific journals during the last few years. Nevertheless, it will be looked upon as the standard book on the subject for many years, we predict. More than half the book is devoted to cell diameters in normal persons; the method of measuring the cells, of drawing the curve, and of calculating the means, standard deviation and coefficient of variation are given in detail; there is a chapter on diurnal variations; if one excludes the early morning reading, which has a mean of about 0.5μ below the mean of all other readings, these are not likely to introduce any error in judging the significance of mean diameters in cases of anaemia, and in any case the Price-Jones curve maintains its normal shape throughout the 24 hours, as well as after violent exercise or forced breathing, though in the former case there is an increase in the mean diameter and in the latter a decrease. As far as pathological conditions are concerned pernicious anaemia is the only one that is gone into in any great detail; this is not surprising as it is the disease on which the author has done most extensive research; however, there are chapters on anaemia following haemorrhage and on microcytic anaemia, and a number of sample curves in such conditions as sprue, aplastic anaemia and polycythemia are given.

Anyone making a serious attempt to investigate blood diseases will find that he is seriously handicapped without a copy of this book, which should certainly be in every medical library in the country.

It is an Oxford Medical Publication.

L. E. N.

APPLIED PHARMACOLOGY.—By A. J. Clark, M.D., F.R.C.P., F.R.S. Fifth Edition. 1933. J. and A. Churchill, London. Pp. x plus 632, with 73 illustrations. Price, 18s.

THE present edition of this book has to a great extent been rewritten. This change was rendered necessary by the increase of knowledge regarding the mode of action of drugs which has been obtained during recent years, and owing to the appearance of the 1932 edition of the British Pharmacopoeia, which forms a satisfactory general guide for selection of drugs for use in therapeutics.

That Professor Clark's book has gone through five editions in the course of a few years amply speaks of the great popularity and demand for the book. As indicated in the preface to the first edition, the author has aimed at bridging the gap between academic and experimental pharmacology on the one hand, and practical therapeutics on the other. In his attempt to do so he has widened the conception of the scope of pharmacology. His inclusion of x-rays, diathermy, electrocution and ultra-violet irradiation in pharmacology cannot be considered irrational on the ground that these are physico-therapeutic measures. There is ample logical reason for their inclusion and this broad outlook gives the book as a whole a unique value. Pharmacology has a direct relationship to physiology,

chemistry and pathology and a proper grasp of the subject is impossible without a knowledge of these sciences. Although the size of the book has prevented the author from giving detailed consideration to these aspects, a short abstract of the physiological and pathological problems concerned is given in all cases and is very helpful to the reader. Professor Clark's book is amazingly up-to-date and contains an account of all the recent investigations regarding the subjects concerned. The chapter on vitamins, the pituitary and sex-gland hormones are worthy of special mention in this respect. The pharmacology of iron salts in the treatment of anaemia is fully described in the light of modern research.

We cannot speak too highly of this volume and are of opinion that the book should be in the possession of all senior medical students in Indian colleges and of practitioners who wish to use drugs rationally. The get-up of the book is excellent and the publishers are to be congratulated on the moderate price of the book.

R. N. C.

MODERN INHALATION THERAPY FOR THE GENERAL PRACTITIONER.—By C. H. Auty, M.R.C.S. (Eng.), L.R.C.P. (Lond.). 1933. William Heinemann (Medical Books) Limited. Pp. vii plus 66. Price, 3s.

The author seeks to prove that the most satisfactory method of administering all drugs and even vaccines is by inhalation and that this method is not only suitable for conditions in which the vapour may come into contact with the diseased area, but also to all morbid states, on the grounds that the mucous membrane of the respiratory tract has more constant and greater absorptive power than that of the alimentary canal. This thesis is not easy to accept and the author does not advance sufficient evidence to warrant its consideration. Further his case is somewhat damaged by loose statements, such as that tuberculosis and rheumatism might be regarded as twin brothers. We find it difficult to believe that for diseases as wide apart as varicose veins and enlarged prostate, the administration of drugs by inhalation is the most appropriate method and we must confess that the author has not converted us to his views.

E. H. V. H.

MODERN CLINICAL PSYCHIATRY.—By Arthur P. Noyes, M.D. Messrs. W. B. Saunders and Co., Philadelphia and London. Pp. 486. Price, 20s.

The author states that this book is the outcome of lectures he delivered to small groups of senior medical students who elected to spend their vacations at the State Hospital for Mental Diseases at Howard, Rhode Island. The book is therefore one eminently suitable for students. The first four chapters are devoted to a few of the basic principles of psychology. The remaining twenty-four chapters deal with the mind in its manifold disorders. The author is happy in the possession of a highly gifted power of exposition and great clarity of expression. He is not didactic, but, at the same time, he does not exhaust the student reader with elaborate disquisitions on the innumerable riddles in mental pathology. The chapter devoted to paranoia and paranoid conditions is particularly worthy of attention. The complicated aetiology of general paresis in respect to its incidence among coloured, as opposed to non-coloured, races is not discussed. This is a great pity because the comparative freedom of Asiatic races, if not those of Africa also, still remains one of the most important of the unsolved riddles of psychological medicine. Each chapter ends with an appropriate bibliography so that any point that may arouse the particular interest of the reader can find further elucidation by reference to the publications cited for that purpose.

The views of the author on what he terms *sexual psychopathy* will probably undergo considerable modification as soon as he comes into touch with the remarkable contributions on this topic of René Guyon, the last of which, 'Sexual Life and Sexual Ethics', has recently been translated into English. Indeed, this criticism is the only one not entirely favourable to the book as a whole that can justly be made.

O. B. H.

THE CLINICAL EXAMINATION OF THE NERVOUS SYSTEM.—By G. H. Monrad-Krohn, M.D., F.R.C.P. Sixth Edition. Publishers: H. K. Lewis and Co., Ltd., London. Pp. xix plus 234, with 64 illustrations. Price, 7s. 6d.

Professor Monrad-Krohn's name has long been associated with neurology and his practical teachings set forth in this book are of great interest. Six editions within 12 years well indicate its usefulness and popularity. The book gives a well-balanced account of numerous clinical tests in neurology with excellent illustrations. The author first deals with the various clinical methods, which cover practically three-fourths of the volume. Then he writes about the electrical tests and cerebrospinal fluid examinations. Lastly, he gives a useful appendix containing outlines of mental examination, anatomical diagrams, pharmacological tests, radiography, etc. The chapters are concise, dogmatic and full of practical directions likely to be of greatest service to students and practitioners. The language is direct and simple and the matter is intelligible to anyone who knows his anatomy and physiology.

R. N. C.

URINARY INFECTIONS.—By C. Morson, O.B.E., F.R.C.S. 1933. John Bale, Sons and Danielsson, Ltd., London. Pp. 76. Price, 2s. 6d.

This recent addition to the Pocket Monograph Series will be welcomed by the practitioner. Within its 74 pages will be found a concise summary of the aetiology, pathology and symptoms of urinary infection together with a description of modern methods of treatment and investigation. The author stresses the importance of testing renal functions when the kidneys are attacked by infective processes, a point which is apt to be overlooked.

In the section on children we think that more prominence should be given to infections other than *B. coli*, and that the importance of tonsillar infections as a cause of pyelonephritis should be mentioned. Apart from this, the book will be found full of useful and essential information.

E. H. V. H.

MIGRAINE: DIAGNOSIS AND TREATMENT.—By R. M. Balyeat, M.A., M.D., F.A.C.P. 1933. J. B. Lippincott Co., Philadelphia and London. Pp. xvi plus 242. Illustrated. Price, 12s. 6d. Obtainable from Butterworth and Company (India), Ltd., Calcutta. Price, Rs. 9-6

The present unsatisfactory state of our conception and treatment of migraine is ample justification for the appearance of a volume devoted to this subject alone. The author has made an exhaustive and comprehensive study, beginning with researches into the hereditary factor and providing many illustrations of the well known fact that migraine is closely linked with other allergic manifestations. He is of opinion that migraine is in practically all cases due to a specific sensitization to one or more foods, though the inherited tendency is an ability to become sensitive rather than an actual sensitization.

The author is to be congratulated on the clarity with which the subject-matter is presented and the care with which the large mass of evidence is analysed. The book opens up new lines of thought and renews our hopes that the ineptitude of our present treatment of this disease may be replaced by the accurate

investigation and the cure of many hitherto intractable cases.

Finally, the opinions advanced are supported by a number of illuminating cases.

E. H. V. II.

PATHOGENIC MICRO-ORGANISMS: A PRACTICAL MANUAL FOR STUDENTS, PHYSICIANS, AND HEALTH OFFICERS.—By William Halleck Park, M.D., and Anna Wessels Williams, M.D. Tenth Edition. 1934. Baillière, Tindall and Cox, London. Pp. x plus 868. Plates 11, figures 215. Price, 35s.

The tenth edition of this well-known textbook on bacteriology has been thoroughly revised and brought up to date. Extensive changes have been made in the sections dealing with active immunization against diphtheria and scarlet fever and recent additions to our knowledge of yellow fever, poliomyelitis, bacteriophage, undulant fever, etc., have been incorporated in this edition. Certain chapters have been revised and brought up to date by workers who have specialized in particular subjects, with the result that the book contains all the latest information.

The comprehensive summary table which gives the essential characters of and pathological conditions caused by the commoner bacteria and which was one of the most useful features of this book has been thoroughly revised and brought up to date. This new edition will undoubtedly prove useful to the student of medicine and we have no hesitation in strongly recommending this book.

C. L. P.

LYMPHATICS, LYMPH AND TISSUE FLUID.—By C. K. Drinker, and M. E. Field. 1933. Published by Baillière, Tindall and Cox, London. Pp. xvi plus 254. Illustrated. Price, 17s. 6d.

IN this book the authors have attempted to summarize what is known of the physiology of the mammalian lymphatic system and also to incorporate some of their own views and experimental findings. There are altogether eight chapters in the book and certain important aspects of the subject, such as the permeability of blood capillaries, the composition of lymph and tissue fluid, the factors concerned in the flow of lymph and the mechanism of disposal of colloidal particles entering the lymphatics, are all dealt with in a magnificently lucid manner. The data presented in the book are of great interest to the physiologist, the pathologist and the immunologist and therefore a perusal of the book will be found highly beneficial by those interested in these subjects. An extensive bibliography of over 68 pages is given at the end and this indeed is a valuable addition.

K. V. K.

VOLUMETRIC ANALYSIS.—By H. P. Starck, M.A. (Cantab.). 1934. Baillière, Tindall and Cox, London. Pp. viii plus 228, with 11 figures. Price, 7s. 6d.

SEVERAL texts, both large and small, have appeared on the quantitative analysis of inorganic compounds both by gravimetric and volumetric methods, and there are also one or two large texts on volumetric analysis alone. The latter are really standard books of reference and are too bulky for an ordinary student. The present text is a handy little volume and the low price brings it within the reach of every student. It is divided into five sections. The first section is an introductory one, making some preliminary remarks and dealing with the theory and proper use of different indicators. The second section deals with acidimetry and alkalimetry, and the third section, which is a large one, is divided into two parts and deals with oxidation and reduction methods. The fourth section deals with precipitation methods, and the fifth discusses some of the applications of volumetric methods to the mixtures of two or more substances. In each example, the reaction is explained briefly with the help of equations,

and the calculations help to make it clear; this is followed by a short description of the procedure to be adopted. The descriptions sometimes appear too brief for a beginner, but an intelligent student cannot fail to grasp it soon. Many examples of the quantitative analysis of organic compounds are found along with the inorganic ones and many of the sections are provided with problems at the end for their solution. From the large variety of examples chosen the book will prove useful not only to the students for university scholarships, national certificates, pharmaceutical, medical and general examinations in chemistry as suggested by the author, but also as a handy and useful companion for post-graduate workers in various laboratories where such quantitative work for determining the purity of compounds is carried out.

S. G.

FORENSIC MEDICINE—CATECHISM SERIES.—By A. Allison, M.B., Ch.B., B.Sc., D.P.H., F.R.F.P.S. (Glas.). Third Edition. E. and S. Livingstone, Edinburgh. Pp. 80. Price, 1s. 6d. Postage 2d.

THE book is well written and ought to be very useful to those for whom it is primarily intended. Though the book is based on European observations, still it helps the students to revise the more important chapters of the subject. It is an excellent cram book and can be safely recommended to students going up for examination.

D. A.

BEHIND THE DOCTOR.—By L. Clendenen, M.D. 1933. William Heinemann (Medical Books) Ltd., London. Pp. xxi plus 458, with 147 illustrations. Price, 21s.

THERE has been a tendency in recent years to write history as a consecutive story of human advancement, rather than as a dull record of past incidents. An example of an attempt of this kind was Mr. H. G. Well's history of the world; Dr. Clendenen's book is such another. In order to fill in the gaps and present the history of medicine in readable form the author has had to draw pen pictures, based on recorded historical facts, on impressions of the customs of the time gained from the literature, and on the assumption that human nature has undergone little change during a period of six thousand years, but nevertheless entirely imaginative as regards actual details. The result is quite satisfactory, in a book written mainly for the layman or the medical man who has hitherto taken little interest in medical history, but the more advanced student of medical history will become a little impatient with the circumlocution entailed in such a method of treating the subject.

We can strongly recommend this book as a very readable introduction to medical history. It is also a book that the doctor can confidently recommend to his patients; from it they will acquire a better understanding and a deeper appreciation of medical science.

L. E. N.

- I. **THE CHEMISTRY AND PHYSICS OF CONTRACEPTIVES.**—By C. I. B. Vogt, B.Sc., Ph.D., F.R.S. (Edin.). Jonathan Cape, London. Pp. 288. Illustrated. Price, 12s. 6d. [Obtainable from Messrs. Butterworth and Co. (India), Ltd. (Publishers), Calcutta.] Price, Rs. 9-6
- II. **CLINICAL CONTRACEPTION.**—By G. M. Cox, M.B., B.S. 1933. William Heinemann (Medical Books) Ltd., London. Pp. ix plus 173. Illustrated. Price, 7s. 6d.
- III. **THE HYGIENE OF MARRIAGE.**—By I. E. Hutton, M.D. Fourth Edition. 1933. William Heinemann (Medical Books) Ltd., London. Pp. 146. Illustrated. Price, 5s.

ONE must assume that there is an almost limitless demand for books on sex hygiene, birth control, and

allied subjects, as we are assured in the prefaces of the books on these subjects, which arrive by almost every mail from Europe, that they are written at the urgent request of some society or to fill 'a long-felt want' of a certain class of reader. We are looking forward to the day when a writer claims, we will not say admits, that she (ninety-five per cent of the writers are women) is writing a book with the object of selling as many copies as possible and making a handsome profit. We do not pretend that medical literature is not richer than it was twenty years ago, by the addition of this type of book, as now at least the medical man does not have to go to the pornographical bookshop to gain the knowledge on sex matters that is necessary to him if he is to advise his patients properly. (The cynic will perhaps say that this is because the pornographical bookshop has invaded the medical library.) But we cannot help thinking that there is much unnecessary duplication, and we feel that it is our duty to select from the pile of books that are sent to us for review only those that, in our opinion, fulfil a special function and fulfil it well.

Each of the three books under review is written for a special class of reader. The first is a record of scientific investigation into the mode of action and the relative efficacy of various drugs and appliances used to prevent conception; it is written for the 'specialist' in birth control, whether he or she be a member of the medical profession or a social worker. For the sake of the latter group of reader many explanatory details, which would be unnecessary for medical readers or non-medical scientists, are given. The investigations reported were undertaken under the auspices of the National Committee of Maternal Health, New York, but the work was carried out in collaboration with Professor Crew of the Animal Breeding Research Department, University of Edinburgh. The book is a valuable contribution to the subject.

Dr. Gladys Cox's book is essentially a medical book, written for medical men and women. No space is given to discussions on the ethics of birth control, though there is a section on its medical indications. After an introductory chapter and a second on the physiology of conception, the author gets down to her subject, and describes and discusses different methods of contraception, as one would different forms of treatment in an ordinary medical book, giving a number of methods with their advantages and disadvantages, their special indications and contra-indications. There is a final chapter on birth control clinics and the position of birth control in the public health services.

Dr. Hutton's book is written for the direct instruction of the public. It is a book that the doctor can confidently recommend to his patients. The subject of the sex relationship of man and woman is discussed openly but entirely inoffensively. There are chapters dealing with birth control, but the subject is not overstressed. We have reviewed earlier editions of this book and we are glad to see that it has now reached its fourth; it is undoubtedly one of the best of its kind.

THE LAST OF THE TABOOS, MENTAL DISORDERS IN MODERN LIFE.—By I. E. Hutton, M.D. William Heinemann (Medical Books) Ltd., London. Pp. 204. Price, 6s.

'THIS book will be of absorbing interest to the general public as well as to social workers, and to those concerned, professionally and otherwise, with the care and treatment of the insane'. So say the publishers. If the word 'should' be substituted for 'will', and 'absorbing' be deleted, the sentence would gain both in modesty and truth. However, if the attitude is taken that the end justifies the means, and if the sentence as it stands increases the sales we will certainly not grudge them their little 'boost', for nobody will be the poorer for reading this book and in some unexpected places it may sow fertile seed.

The title and sub-title together give a clue to the trend of the book. The author claims that nowadays every subject is discussed freely (even the most intimate details of sex relationship, and in this field the author can certainly claim to have played her part in tearing away the veil of false modesty) with the single exception of mental disease. The average individual, especially the average woman, and the writer being a woman has probably suffered this type of confidence, is prepared to discuss in great detail her husband's bowels, or even a plithical cousin, but maintains a rigid silence about an uncle who is in a mental asylum. The writer's contention is that she should be willing to discuss the last-named as freely as the other subjects, and in fact talk of the mental homes she herself has been in, as openly as she would her visits to Bath or Harrogate. The subject of mental disease is not a very pleasant one, neither is that of bodily disease, and, if people are prepared to discuss the latter (and they are—*ad nauseam*), they should not so studiously avoid the former subject.

The medical profession is largely to blame because they pander to these unreasonable prejudices of their patients; they refer to a condition as a 'nervous breakdown' and call in a nerve specialist, when they should really diagnose 'manic-depressive insanity' and call in a mental specialist.

Finally, the Law of the Land is arraigned. Certification is far too complicated a process. Two doctors and a magistrate have to see the patient within a prescribed period; this is often difficult to arrange, it frightens the patient, and gives a wrong impression to the relatives. It should be as easy to send a patient to a mental asylum as it is to a fever hospital; it would then not be looked upon as a serious event, and the last of the taboos would be short-lived.

L. E. N.

AIDS TO BOTANY.—By H. J. Bonham. 1934. Baillière, Tindall and Cox, London. Pp. viii plus 221, with 47 figures. Price, 3s. 6d.

THIS small book on botany is written in such a simple language that it will be found very useful to the beginner. It contains the essentials of the subject presented in a concise manner. The inclusion of the common Natural Orders of the flowering plants enhances the value of the book. The simple notes on plant ecology and variation, heredity, Mendelism and evolution will be very interesting to a novice. Although the subject-matter does not completely cover the I.A., and I.Sc. course of the Indian universities, it will be a very useful companion to the textbook.

E. G.

THE CONJOINT FINALS.—By G. N. Beeston, M.R.C.S. (Eng.), L.R.C.P. (Lond.). Second Edition. 1933. John Bale, Sons and Danielsson, Ltd., London. Pp. vi plus 158. Price, 6s.

THE sub-title of this book, 'A reproduction of all the questions set in medicine, surgery and midwifery from 1911 to 1932 classified under the various systems and arranged in the date-order of their occurrence, together with a new section on pathology and bacteriology', is self explanatory. It will not only be found useful to students going to England to take the Conjoint Board examinations, but to teachers and examiners in this country, as a guide to their teaching and to provide suggestions for questions they are required to set in examinations in this country.

MEDICAL ENTOMOLOGY ON CHART.—By R. C. Acharyya, D.T.M. 1934. To be had at 12, Bipradas Street, Calcutta. Price, Rs. 2. Postage extra.

THIS is another example of literature perpetuating the terrible caste system of Linnæus. Within this

hidebound system, however, the author has compiled a very useful table, showing in only two sheets the important characters of his phyla and other castes.

While he should have got some entomologist friend to correct such mistakes as 'Solifugae or whip scorpions' and some pedagogue to object to the spelling Newzeland, for New Zealand, his main object, of enabling students who use it to pass their examinations, will doubtless be assured.

The amount of care put into the disposition of the group in the tables is most praiseworthy as also is the get-up of the publication.

Dissecting Aneurysms. By T. Shennan. 1934. Special Report Series, No. 193. (Medical Research Council). Published by His Majesty's Stationery Office, London.

Abstracts from Reports

THE ANNUAL REPORT ON THE WORKING OF THE CIVIL HOSPITALS AND DISPENSARIES IN THE MADRAS PRESIDENCY FOR THE YEAR 1932. BY MAJOR-GENERAL C. A. SPRAWSON, C.I.E., V.H.S., I.M.S., SURGEON-GENERAL, WITH THE GOVERNMENT OF MADRAS

Number of hospitals and dispensaries.—The total number of medical institutions of all classes working in the Presidency at the beginning of the year under report was 1,337 (1,091 in rural areas and 246 in urban areas), 30 new dispensaries were opened, 20 were closed and 10 were transferred to other classes during the year.

Visited-dispensary system.—The 'visited-dispensary' system previously known as 'dispensary-doctor' system which allows a medical officer or practitioner to leave his permanent dispensary where there is not sufficient work to engage him fully, on two fixed days a week at specified hours in order to travel with his appliances to another village or villages close by and render medical aid there, has been working only in six districts and in the Vizagapatam Agency. This system can be considered satisfactory only in a few exceptional places or with exceptional individuals to work it. It is not proposed, therefore, to extend this method of medical relief as a whole but to employ it only when particular circumstances indicate that it may be used advantageously.

Nursing staff.—For the first time in the history of the nursing service in this Presidency, the number of qualified nurses who were available for appointment as staff nurses after the examinations held in June and December 1932 were in excess of the number of vacancies available for them.

Midwives.—At the instance of the Madras nurses and midwives council, a scheme of training and examination of candidates for the vernacular course in midwifery in Government hospitals was sanctioned by Government. The Madras nurses and midwives council have, during the year 1932, recognized four institutions as training centres for midwives for the scheme sanctioned. On 31st December, 1932, the council had on its registers 780 nurses, 1,668 midwives and 7 dais.

Antirabic treatment.—A higher dosage of 5 per cent carbolyzed vaccine for the treatment of both civil and military patients was introduced at the Government General Hospital, Madras, from 1st June, 1932. No new centres were opened during the year.

Leprosy.—In view of the successful working of the group leprosy scheme sanctioned for two years from 1st May, 1931, its continuance has been sanctioned for a further period of two years from 1st May, 1933. The year under report is characterized by increased activities and by the organization of an intensive anti-leprosy campaign by social workers in Salem district. Several medical officers especially those in charge of leprosy clinics were given training in the treatment of leprosy. About 120 leprosy clinics were opened during the year bringing the total number of such clinics throughout the Presidency to 196.

The awakening of so many in the Salem district to a sense of citizenship and co-operation and the popular enthusiasm that has led to the erection by private donors of leprosy clinics, operating theatres, maternity wards and other needed buildings have been the most striking features of the medical year throughout the Presidency.

With a view to affording greater facilities to Government servants for leprosy treatment, the Government have recognized fourteen additional medical institutions as treatment centres for leprosy during the year.

Many district and taluk boards have not yet realized the utility of the leprosy campaign with the result that several areas where clinics are very essential are yet untouched. It is hoped that the local bodies will soon realize the importance of the survey of leprosy and of propaganda and contribute towards the successful development of the work. An intensive campaign against leprosy can be revived under these heads—Treatment, propaganda, survey, school medical inspection and social service.

Veneral diseases.—The venereal department of the Government General Hospital, Madras, under Dr. R. V. Rajam, M.B., M.S., has worked satisfactorily. In the course of the year, 6,846 cases were examined and treated at the General Hospital. A little more than 90 per cent of the patients have been treated as out-patients. Venereal clinics have been opened in the following mofussil medical institutions:—Headquarters Hospitals at Coimbatore, Cuddapah, Masulipatam, Madura, Calicut, Nellore and Tanjore; Women's and Children's Hospitals at Calicut and Negapatam and Government Hospital, Rajahmundry. It is expected to open more clinics in the mofussil as funds become available for the purpose.

Honorary medical officers.—Revised rules regarding honorary medical officers have been issued by Government. Applications from candidates for honorary appointments with reference to the revised rules have been invited by advertisement and proposals have been sent up to Government for the appointment of suitable candidates as honorary medical officers.

THE REPORT ON THE WORKING OF HOSPITALS AND DISPENSARIES IN THE PUNJAB FOR THE YEAR 1932

THE Medical Department, perhaps more than any other, has felt the full effect of the unprecedented financial stringency which Government have had to face in recent years. Being a beneficent department, it has no financial resources of its own, but depends for its progress and expansion entirely upon Government grants. When these grants are restricted to the barest necessities, it is to be expected that the annual record of the department would not be one of continued advance, and therefore it is sufficiently gratifying that it is one of sustained activity.

The Royal Commission on Agriculture in India recommended that vital statistics for rural areas should include particulars of the strength and distribution of the medical and health services including trained

midwives. Acting on this recommendation, the Government of India directed, *inter alia*, that the provincial reports on hospitals and dispensaries should be amplified so as to give the number of medical institutions in urban and rural areas separately, and that a new table should be added to these reports showing the strength and distribution of the medical and health services, including trained midwives, in these areas. In accordance with these instructions, statement A, which appears in this report, has been amplified, for the first time, so as to give the details required by the Government of India, and a new table, which appears as an annexure to statement A, has been added showing the strength and distribution of the medical and public health services, including trained midwives, in rural and urban areas in each district in the province.

This new table is very instructive inasmuch as it shows the concentration of trained women—midwives and nurses—in urban areas. Of the 29 districts of the province, 18 cannot boast of a single trained woman worker in rural areas. Thus, although much has been done in extending qualified medical aid by women to women in rural areas in some of the districts, a great deal remains to be done in others; and it is to be hoped that more and more trained women workers will be available for ministering to the needs of women in rural areas as enlightenment spreads and weakens the force of 'custom', which, unfortunately, still hampers medical activity in this direction.

Of a total of 414 trained nurses and midwives employed in the province, only 43 work in the rural areas, and, of the latter, half the number are employed in the districts of Kangra and Karnal alone.

The beginning of the year 1932 saw 1,001 dispensaries of all classes in operation. Seven more were opened during the course of the year while 31 were closed, and one transferred from class IV to class I, leaving 974 working at the close of the year. The dispensary shown as transferred from class IV to class I is the Lady Aitchison Hospital, Lahore, which was provincialized during the year, and its classification thus changed from 'class IV private aided' to 'class I state public'. Canal dispensaries and the dispensaries maintained from local funds account for the largest number (26) of the closures; the other 8 dispensaries closed being: departmental institution 1, private aided 2, private non-aided 2 and railway 3. The newly opened dispensaries include 4 railway, 2 local and municipal fund and one private non-aided.

Subsidized dispensaries.—In the district of Attock two of the rural dispensaries were transferred to the charge of private practitioners and a new class thus established which may be designated 'subsidized dispensaries'. The general scheme of work of this class of dispensaries is as follows:

A private practitioner is placed in charge of a dispensary and is given Rs. 25 per mensem by way of a subsidy. The practitioner thus placed in charge of the dispensary is not liable to be transferred to another dispensary without his consent but in other respects is subject to the same conditions of service as the whole-time medical officers in charge of rural dispensaries. A whole-time dispenser who is an employee of the district board is appointed to the dispensary on a salary of Rs. 25 per mensem and a grant of Rs. 500 per annum is given for drugs and instruments. The total cost of such a dispensary is thus Rs. 1,100 against Rs. 2,500 that of a rural dispensary under the existing scheme. The practitioner has to make his own arrangements for menial servants and for any miscellaneous expenditure connected with the dispensary. He is also entitled to charge for medicines supplied to patients, except to the very poor, in accordance with a scale which lays down the maximum chargeable in this manner.

The scheme is being tried as an experiment, and it remains to be seen whether it is going to be a success or not. Should it prove successful, it is obvious

that it will make it possible to expand medical relief all over the province to a much greater extent than has been possible hitherto.

Provincialization.—For reasons of economy, the scheme of provincialization of hospitals and dispensaries also has come to a standstill, and no new hospitals or dispensaries, maintained by local bodies, were provincialized during the year under report. As stated in the report for 1931 there are 67 hospitals and dispensaries which remain to be provincialized and taken over by Government, and this will be done as soon as financial considerations permit.

Medical aid for women.—Remarkable improvement in this respect took place in the Attock district in the year under report. The Anant Ram Zenana Hospital at Tallagang in the Attock district was opened during the year under report and the women's section of the civil hospital, Campbellpur, was placed in charge of a woman sub-assistant surgeon. A travelling woman sub-assistant surgeon was also appointed in the same district, with headquarters at Jand. On the other hand, there was a set-back in some of the places in the same district. The women's hospitals at Bhera, district Shahpur, and Narowal, district Sialkot, which were maintained by Mission authorities were closed during the year. Sirsa, Panipat, Chiniot and Shorkot remained without women sub-assistant surgeons as the local bodies concerned were unable to secure the services of lady doctors on the scales of pay sanctioned by them. The most noteworthy feature of the year, however, is that the Lady Aitchison Hospital, Lahore, was provincialized.

There are at present only 42 (or 44 including two private non-aided hospitals at Bhiwani and Ambala Cantonment) separate hospitals for women in the Punjab in charge of women doctors and 21 more lady doctors are attached to the women's sections in the general hospitals.

Women sub-assistant surgeons attached to the provincialized taluk hospitals and dispensaries are also now required to examine medically school girls in their vicinity. The main object of the scheme is to popularize medical relief among women and it has, therefore, been impressed upon the women doctors that they should make every effort to get into touch with the school mistresses and mothers of the girls in order to inspire confidence in them. Further, they have been instructed to make a point of giving health talks to women on matters of personal hygiene and on causation, prevention and treatment, etc., of minor ailments. It is hoped in this manner to make the hospitals even more popular than at present.

Medical education for women.—The Punjab Medical School for Women which is incorporated with the Women's Christian Medical College for Women, Ludhiana, was hitherto the only institution on which the province depended for its supply of lady doctors required for the charge of hospitals and dispensaries for women. But to meet the growing demand among women for medical education of the degree standard, the system of co-education was introduced in the King Edward Medical College, Lahore, in the year 1929 and extended to the Medical School, Amritsar, during the year under report. These institutions which are primarily intended for men students now also train women for the M.B., B.S. degree of the Punjab University and the 'L.S.M.F.' diploma of the Punjab State Medical Faculty. Up to 10 seats are reserved annually for the admission of women students to the King Edward Medical College, Lahore, and the number of women students to be admitted to the Medical School, Amritsar, has now been raised from 10 to 15. There were 20 and 13 women students on the rolls of these institutions respectively at the end of the year 1932. The system of co-education in these two medical institutions appears to be working satisfactorily.

As women's education in the province is advancing very rapidly, the number of girls seeking admission to medical colleges and schools is fast increasing.

The accommodation in the existing institution is very limited, and more and more candidates find it difficult to secure admission every year. The necessity for the separate medical school for women which the Government contemplated to establish at Lahore is thus obvious, and it is to be hoped that ways and means of bringing it into existence will soon be forthcoming.

Training of nurses and midwives.—In order to meet the demand from the Indian public for the provision of facilities for the training of Indian girls as nurses, a scheme was sanctioned during the year under report to permit of Indian women joining the hospitals as probationers, staff nurses and nursing sisters. Indian nurses are required to adopt the same style of living as the European and Anglo-Indian nurses attached to the hospitals but are permitted to wear *saris* if they should desire to do so. The scheme has been only recently introduced and its progress will be watched with interest.

An Act to provide for the registration and better training of nurses, health visitors, midwives and dais in the Punjab was passed during the year under report, and came into force in the province with effect from the 3rd September, 1932. Steps are being taken to establish the nurses' registration council provided for in the Act.

There is no regular examining body for the examination of nurses at present. All the training hospitals conduct their own examinations and give diplomas. It will be for the new nurses' council to determine if any departure from this should be made. It seems desirable that a central examining body like the Punjab State Medical Faculty should take over this important duty.

The Punjab Central Midwives' Board continued to discharge the important function of supervising the training and conducting the examinations of midwives of all grades. Several changes in the rules have been under consideration with a view to providing large facilities all over the province.

SUPPLEMENT TO THE ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF ASSAM FOR THE YEAR 1932

Abstract of a report on the yaws campaign in Kamrup district

THE credit of identifying the disease in this district belongs to Dr. N. C. Dey, Sub-Assistant Surgeon, of the then Khetri kala-azar dispensary in 1929. He started the treatment on a small scale with drugs purchased by the patients themselves. A full account was published by Dr. Dey in the *Indian Medical Gazette*, August 1930, but treatment was suspended early in 1930 partly because the patients were unable to pay for continued treatment and partly because the value of prolonged treatment was not realized at the time.

In January 1931 Captain FitzGerald, who had become interested in the work commenced by Dr. Dey, and had been impressed by the large number of cases shown to him by the latter, decided on more thorough investigation and more systematic methods of treatment and observation, using a supply of drugs which were kindly provided by their various makers for trial. In April 1931 the first grant (Rs. 1,000) was made available by Government for the purchase of drugs.

DISTRIBUTION

The disease is confined in the western part of the district mainly in areas between the South Assam Trunk Road and the Khasi Hills, in the eastern part it is to be found in villages situated at the foot of the hills on either side of the trunk road up to and beyond the Nowgong border. To what extent it prevails in Nowgong district can be gauged only roughly from the number of cases that attend the most eastern centre at Verakuchi. From the north of Digaru (Assam-Bengal Railway) cases come from the Mayang

group of villages (Nowgong district) and from the areas in the vicinity of the Panbari and Panikhati railway stations close to Gauhati.

In the endemic areas to the east of Gauhati the disease is chiefly confined to the Mikirs, Jalungs, Garos, Kacharis and Rabhas, to the west to the Garos, Khasis, Kacharis and Rabhas, although the disease has been seen amongst the Koch caste in the eastern part of the district. Lately one better class Hindu, a Mohammedan and a Nepali living in villages in close contact with these cases have been found with the disease.

A questionnaire addressed by the civil surgeon to sub-assistant surgeons in charge of dispensaries in this district did not reveal a single case having been treated in 1930. Nor is it a matter of surprise that the people do not present themselves for treatment for, unless the condition is recognized and arsenicals given, this is found to be useless.

There is no doubt that yaws exists to a hitherto unsuspected extent in the Assam Valley and probably in the Surma Valley as well. One is inclined to think that many of the venereal cases treated in the campaign amongst the hill tribes might have in reality been undiagnosed yaws.

Economically this condition is of great importance as the period of maximum disability coincides with that of planting and tending the crops. Indeed all yaws lesions become worse in the damp heat and there is a tendency for them to improve during the colder months.

ORGANIZATION

Treatment is afforded by the two public health dispensaries, *viz.* Digaru and Hahim, which are situated in the yaws endemic areas. The dispensary at Digaru with its sub-centres really serves a stretch of land about 35 miles long. At each of these centres kala-azar and leprosy are also being treated. The yaws campaign began in a very small way and has steadily progressed.

The assistant surgeon, public-health department, Nowgong, was trained in the technique of diagnosis and treatment at the Digaru dispensary and its sub-centres in December 1932 and a centre at Morigaon was opened in Nowgong district.

The assistant surgeon, public-health department, Goalpara, was also trained at Digaru and its sub-centres in June 1933 and a treatment centre at Agiya is being opened shortly.

TREATMENT

It has been found by experience that yaws is characterized by the extreme chronicity of the condition and requires prolonged treatment in all but its earliest stages; this is contrary to the general impression given in textbooks that yaws is readily cured by one or two injections of N. A. B.

Of 263 cases treated by Dr. Dey in 1929-30, 141 cases were traced subsequently.

These cases had been treated with injections of 0.3 or 0.45 grammes of N. A. B. and the number of injections received by each case is shown below:—

	Total	Clinical relapse	SERUM	
			Positive	Negative
One injection	101	47	34	20
Two injections	29	12	11	6
Three injections	7	3	2	2
Four injections	2	1	1	0
Six injections	2	2	0	0
	141	65	48	28

Of these 65 showed clinical relapse prior to 1931 and sera of the remaining 76 cases were examined at the

Pasteur Institute showing 48 positive and 28 negative. Thus of the whole series 20 per cent only could be regarded as permanently cured (and the cure rate was the same whether they received one or more than one injection.—*Editor, I. M. G.*)

Various synthetic arsenicals and preparations of bismuth were used either alone or in combination.

Sera of cases are sent to the Pasteur Institute, Shillong, for examination after absence of a clinical relapse for periods of six months to a year. Batches of sera are also examined by the Sachs-Georgi method at the Sadr hospital, Gauhati.

Correspondence

A CASE OF HYDROPHOBIA AFTER PREVENTIVE INOCULATION

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In your February 1934 issue, page 81, you have published a case of 'Hydrophobia after Preventive Inoculation' with your note of comment.

I hasten to give you a case which will interest you, I am sure.

My youngest brother aged three years was bitten by a rabid dog, unprovoked, in 1909; I forget the exact month. I managed to kill the dog and sent it to the veterinary surgeon, Trichinopoly! I took the child immediately to the Pasteur Institute, Coonoor, as the wounds were all on the face. The boy underwent fourteen days' injection treatment and I reported his good health six months later. However, after a year he suddenly developed signs of hydrophobia and died. I can assure you that he was not bitten a second time by any dog after he got 'cured' by the injection treatment.

These were incidents before I entered the medical course, but I vividly remember to-day the whole thing. Certainly there ought to be some difference between 1909 treatment and 1933 treatment. Or are we on the same ground as 1909?

Yours, etc.,

S. RAMADAS, L.C.P. & S. (Bom.),
L.M.S. (Lond.), L.R.C.P. (Lond.), M.R.C.S. (Eng.),
Assistant Surgeon.

MUNICIPAL HOSPITAL,
NANDYAL,
28th February, 1934.

[Note.—We sent a copy of this letter, with further details supplied by our correspondent, to the Director, Pasteur Institute of Southern India, Coonoor, who confirmed the fact that this boy underwent a full course of treatment from the 6th March, 1909, to 19th March, 1909, and added the following comment: 'The period of observation of treated patients was then only three months, and he was certified by the District Medical and Sanitary Officer, Trichinopoly, on the 19th June, 1909, to be alive and well.'

The fact of the death of the patient was not communicated to this office.—*Editor, I. M. G.*

Service Notes

APPOINTMENTS AND TRANSFERS

MAJOR-GENERAL SIR ROBERT MCCARRISON, Kt., C.I.E., K.H.F., an officer of the Medical Research Department, was placed on foreign service under the Indian Research Fund Association, from the 14th May, 1933, to 20th May, 1933, and from 8th August, 1933, to 13th August, 1933, while he was on deputation in connection with the Second International Goitre Conference held at Berne in August 1933.

The services of Lieutenant-Colonel C. M. Plumptre, Officiating Superintendent, St. George's Hospital,

Bombay, are placed at the disposal of the Government of Madras, for employment as Professor of Midwifery, Medical College, and Superintendent, Government Hospital for Women and Children, Madras, with effect from the date on which he assumes charge of his duties.

Major S. Nag, Civil Surgeon, Murshidabad, is appointed as Civil Surgeon, Jalpaiguri.

Major P. C. Banerji, Civil Surgeon, Bakarganj, is appointed as Civil Surgeon, Chittagong.

Major B. G. Mallya, Civil Surgeon, Chittagong, is appointed as Civil Surgeon, Howrah.

Major W. M. Will, Officer-in-Charge, Medical Store Depot, Bombay, is appointed to officiate as Assistant Director-General, Indian Medical Service (Stores), during the absence of Lieutenant-Colonel Sweet, D.S.O., on leave.

The services of Major L. S. Mody are placed at the disposal of the Government of the Central Provinces for employment in the Jail Department, with effect from the 10th February, 1934.

Major S. R. Prall is appointed to officiate as Superintendent, St. George's Hospital, Bombay, with effect from the afternoon of the 2nd March, 1934, pending further orders.

The unexpired portion of the leave granted to him is hereby cancelled.

Captain J. C. Drummond is appointed, until further orders, as Civil Surgeon, Hooghly.

The services of Captain Hoe Min Sein are placed temporarily at the disposal of the Government of Burma, with effect from the 26th February, 1934.

The services of Captain J. E. Gray are placed temporarily at the disposal of the Government of Bombay, with effect from the afternoon of the 31st January, 1934.

Captain S. M. K. Mallick, an officer of the Medical Research Department, is appointed as a Supernumerary Officer at the Central Research Institute, Kasauli, with effect from the date on which he assumes charge of his duties.

The services of Captain J. F. Shepherd are placed temporarily at the disposal of the Government of Madras, with effect from the 13th February, 1934.

The services of Captain M. H. Shah are placed at the disposal of the Government of the Punjab, for appointment as Officiating Medical Superintendent, Punjab Mental Hospital, Lahore, with effect from the afternoon of the 31st January, 1934.

Captain H. S. Waters is appointed to hold charge of the duties of the post of Presidency Surgeon, Bombay, in addition to his own duties, *vice* Lieutenant-Colonel A. N. Thomas, D.S.O., proceeding on leave, with effect from the afternoon of 5th April, 1934, or subsequent date of relief.

Captain R. Linton, Civil Surgeon, Midnapore, is appointed as Civil Surgeon, Mymensingh.

To be Captains (on probn.)

R. K. Misra. Dated 11th January, 1933, with seniority 2nd April, 1925.

A. N. Duggal. Dated 21st May, 1933, with seniority 19th May, 1930.

A. A. Pullar. Dated 12th February, 1934, with seniority 12th January, 1934.

To be Lieutenants (on probn.)

5th February, 1934.

R. L. H. Minchin, with seniority 5th February, 1932.

W. G. Kingston, with seniority 28th April, 1932.

Richard de Soldenhoff, with seniority 5th February, 1933.

R. R. Prosser.

J. Scott.

J. Edis-Myers.

T. K. White.

D. W. Taylor (Seconded).

C. J. Hassett.

S. G. O'Neill.

F. J. Doherty.

J. W. D. Goodall (Seconded).

Lieutenant B. F. B. Russell is restored to the establishment, 5th February, 1934.

To be Lieutenants (on probn.)

C. B. Miller, 13th February, 1934 (Seconded).
E. Parry, M.B., 15th February, 1934.
W. G. Kennedy, M.B., 19th February, 1934.

LEAVE

Lieutenant-Colonel A. N. Thomas, D.S.O., Presidency Surgeon, Bombay, is granted leave in India for a period of 1 month and 6 days, with effect from the afternoon of the 5th April, 1934, or subsequent date of relief.

Lieutenant-Colonel R. Sweet, D.S.O., Assistant Director-General, Indian Medical Service (Stores), is granted combined leave for 12 months, with effect from the 30th March, 1934, or subsequent date from which he may avail himself of it.

PROMOTIONS

Colonel Sir R. McCarrison, Kt., C.I.E., K.H.F., to be Major-General, 19th July, 1933.

Colonel D. P. Goll to be Major-General, 16th November, 1933.

Lieutenant-Colonels to be Colonels

H. C. Buckley. Dated 24th October, 1933, with seniority 1st August, 1928.

C. H. Reinhold, M.C. Dated 16th November, 1933, with seniority 1st March, 1929.

Majors to be Lieutenant-Colonels

Dated 1st February, 1934.

N. S. Jatar, D.S.O.

M. L. Treston.

A. Chand.

R. Lee.

T. S. Shastri.

C. deC. Martin.

J. H. Smith.

Dated 6th February, 1934.

J. B. de W. Molony, O.B.E.

K. R. Batra.

B. H. Singh, M.C.

O. R. Unger.

A. H. Hart. Dated 7th February, 1934.

N. Briggs. Dated 10th February, 1934.

F. R. Thornton, M.C. Dated 11th February, 1934.

R. L. Vance. Dated 15th February, 1934.

F. Griffith. Dated 8th March, 1934.

J. P. Huban, O.B.E. Dated 23rd March, 1934.

Lieutenants to be Captains

F. A. B. Sheppard. Dated 2nd February, 1934.

M. K. Bryce. Dated 3rd February, 1934.

J. L. O'Neill. Dated 3rd February, 1934.

Lieutenants to be Captains (provl.)

E. H. Lossing. Dated 4th August, 1933.

M. Sendak. Dated 2nd February, 1934.

R. J. Jarvie. Dated 2nd February, 1934.

Lieutenant (on probn.) to be Captain (on probn.)

H. H. Mahmood. Dated 10th February, 1934.

Lieutenants to be Captains (Temp. Comms.)

Dated 9th March, 1934.

T. R. Pahwa.

M. A. Gaffar.

J. N. Vasudeva. Dated 26th March, 1934.

RETIREMENTS

Major-General W. V. Coppinger, C.I.E., D.S.O., 16th November, 1933.

Major-General J. D. Graham, C.B., C.I.E., K.H.S., retires 28th February, 1934.

Colonel L. Cook, C.I.E., 24th October, 1933.

Lieutenant-Colonel S. J. Bhatena. Dated 24th January, 1934.

RELINQUISHMENTS

The following relinquishments are permitted, subject to His Majesty's approval:—

INDIAN MEDICAL SERVICE. (Temp. Comms.)

Captain B. Singh. Dated 29th October, 1933.

Captain J. M. Gole. Dated 18th December, 1933.

RESIGNATIONS

The Governor-General is pleased to accept the resignation by the Honourable Major-General C. A. Sprawson, C.I.E., K.H.F., of his office of Member of the Council of State.

Notes

WATSON'S MICROSCOPIC RECORD

Watson's *Microscopic Record* is far from being an ordinary disguised trade circular. In each number will be found useful, disinterested hints to microscopists, as well as a description of the latest productions of this firm which cannot fail to interest both medical and non-medical users of the microscope.

The recently-issued number contains, amongst other interesting articles, a description of the mica-sheet method of making microscopic preparations. This method will appeal more particularly to the lecturer or demonstrator as it provides him with an easy way of preparing and staining uniformly a large number of sections for distribution to his students. The method consists in fixing sections, or other specimens, on mica sheets, which are then stained and counter-stained, dehydrated and cleared in the ordinary way. The mica sheet can be stored or used immediately, as circumstances dictate; in the latter case, it is cut up with a fine pair of scissors and the sections

distributed to the class for mounting on ordinary microscopic slides.

The number contains other interesting notes, for example on dark-ground illumination and on 'polarizers'.

DESCRIPTION OF PNEUMATIC TOURNIQUET

By H. C. SINDERSON, M.D., F.R.C.P.

DR. H. C. SINNERSON, Professor of Medicine, Royal College of Medicine, Baghdad, has devised a small pneumatic tourniquet for use in intravenous injections. The tourniquet consists of a rubber inflation bag under 5 inches long and less than 2 inches wide. One inch from one end is attached a piece of rubber tubing to which a small inflating ball with control valve is connected. The inflation bag, which lies flat when deflated, is contained in a washable cloth armlet, 36 inches in length and tapering to half an inch at the tail end. The bag is placed very loosely over the

front of the upper arm just above the bend of the elbow (as in sketch) with the inflation ball lying laterally in a pillow on which the elbow rests. The arm band is wrapped over the bag as with a bandage, the last two or three inches being tucked into the final fold.

The screw of the control valve is closed and the bag inflated. The needle is introduced into the vein and the valve then opened. Deflation is almost immediate and the injection is made with the appliance still in position, where it remains until the operation is completed.

The appliance is extremely small and simple to use; injection can be made without any adjustment of the bag after application and a further advantage claimed

is that, as the rubber bag is limited in position to the front of the arm, no movement of the limb is associated with deflation.

The tourniquet has been made by Messrs. Down Bros. and can be obtained complete, in leather case, for fifteen shillings and six pence.

LIVER EXTRACT B.D.H. (FOR INJECTION)

FOLLOWING the work of Minot and Murphy on the administration of liver in the treatment of pernicious anaemia and the work of Cohn and his associates on the development of methods of preparing liver extracts containing the hæmatopoietic principles, much research has been carried out in investigating the chemical nature of the anti-anaemic factor or, as it is called, the *pernicious anaemia fraction* of liver. Early attempts at preparing this fraction in such a state of purity as to warrant its injection as a routine method of liver medication resulted in the issue of products which produced serious depressor effects, while the therapeutic action showed little or no advantage over that produced by the oral administration of liver extract prepared by the method of Cohn.

As a result of a series of investigations in the B.D.H. laboratories a method has been worked out for preparing the anti-anaemic factor of liver, free from protein and in a highly purified form. This is now presented in a sterile isotonic solution suitable for general medicinal use by subcutaneous, intramuscular or intravenous injection.

One cubic centimetre of this solution, the amount recommended for one injection, is equivalent in anti-anaemic potency to 50 grammes of fresh liver, whilst its depressor effect does not exceed that of a 0.0005 per cent solution of histamine acid phosphate when introduced by the intravenous route into an etherized cat.

The issue of Liver Extract B.D.H. (for injection) meets the need for a concentrated liver preparation which can be relied upon for unfailing therapeutic action without any deleterious after-effects, either local

or general; furthermore, the product is entirely British.

It is not suggested that the treatment of pernicious anaemia by the injection of liver extract should replace the more general method of oral administration; on the contrary, the oral administration of liver extract will continue to be the routine method in the vast majority of cases of pernicious anaemia, and no patient who is making satisfactory progress through this method will need to be treated by injection. There are patients, however, to whom a pure, highly-active liver extract for use by injection will come as a boon; for example, there are those patients who are severely ill and cannot take medicine in any form by the mouth, also those patients who, on account of gastric disability, cannot tolerate powdered liver extracts when administered orally. Furthermore, there may be occasions, particularly among hospital cases, when it is exceedingly important to obtain a maximum reticulocyte response in the minimum time in order that the patient may be released from hospital as soon as possible, subsequent treatment at home taking the form of the oral administration of a daily maintenance dose of liver extract; in these cases a series of injections of a highly potent preparation will produce the effect of a comparatively long course of oral treatment, the advantage of injection over oral treatment being that the former is far more rapid in its effect than the latter.

DOSAGE

Liver Extract B.D.H. (for injection) has been tested clinically, and highly satisfactory results have been reported. In the majority of cases it is found that one intramuscular injection daily produces a quick response, and even in such cases as are in *extremis* the improvement is rapid; indeed, after one injection of 1 to 2 c.cm. daily for three or four days in most cases the patient can leave hospital and thereafter be able to adopt the oral method and to take the necessary daily maintenance dose without difficulty.

It is used in the form of a sterile isotonic solution in the form of ampoules of 1 c.cm. each containing the anti-anaemic principles of 50 grammes of fresh liver.

REMOLYSIN

REMOLYSIN. it is claimed, by supplying the glandular deficiencies, not only brings about a reduction of fat in a woman, but also tends to have a tonic effect on the entire body.

Remolysin supplies the glandular substances in a desiccated tablet form and may be taken over a considerable period without undesirable by-effects. Its purity and physiologic activity is warranted by a concern which for many years has specialized in hormonal preparations of exceptional merit.

In prescribing Remolysin, it is well to order small doses at the start (see directions), regulating the increase according to the tolerance of the patient and the amount of weight lost. The decrease should be gradual and not exceed fifty pounds from a person of two hundred pounds.

Further information may be had by writing to the Remogland Chemical Co., 25, West Broadway, New York City, or to the local distributors, namely Smith, Stanistreet and Co., Calcutta, and Kemp and Co., Bombay.

EUROPE'S MOST MODERN HOTEL

THE following news item has been received from London. It seems possible that medical visitors from India, who are strangers to London, may like to know of some reasonably-priced accommodation to which they can go immediately they arrive:

Visitors to London will now be able to stay at the most modern hotel in Europe.

In their bedrooms there they may choose their own climate. The moving of a small valve lever will regulate the temperature of each room to the climate of the land from which its occupant comes. Americans and some visitors from the Continent like to sleep in an atmosphere as hot as 70 degrees. The average Englishman, however, prefers one of 55 degrees or even cooler.

This hotel is at the Marble Arch, with a view over Hyde Park that is among the finest in London. Its name is the Cumberland, and it was opened on the 12th December, 1933.

There are 1,000 bedrooms, each with its own bathroom, toilet, and lobby. Yet the charges are modest.

A single bedroom with private bathroom and table d'hôte breakfast will cost 11s. 6d., and a double bedroom with private bathroom and two breakfasts will cost 19s. 6d.

VITAMINS A, B AND D

THE significance of the vitamins as vital hæmatopoietic factors in certain types of anæmias was not fully appreciated until recent work in hæmatology led to the elucidation of the factors essential to hæmatopoiesis. The work of *et al.* is based on experimental work and is now advanced that sprue,

coeliac disease, and tropical megalocytic anæmia are in some way connected with vitamin B, probably B₁₂, deficiency. This suggestion receives support from the fact that it has been demonstrated that anæmia, in association with coeliac disease and tropical megalocytic anæmia, is responsive to yeast preparations and that these diseases can be cured by a well-balanced diet. As far as is known at present, however, these special types of megalocytic and the microcytic nutritional anæmias only will respond to this treatment, as it has been shown that Addisonian pernicious anæmia, although a deficiency disease, as a result of the deficiency of the specific anti-anæmic factor found in the liver, will not respond to yeast preparations.

This introduces a useful concept as to the possible mode of action of the vitamins and suggests that in some instances deficiency diseases may be due to lack of effective interaction between some substances in the gastro-intestinal tract and the essential vitamin, rather than to a defective diet.

It is noteworthy that recent work indicates that the lymphadenoid type of goitre is related to deficiency of vitamins A, B and C in the diet, and that the absence of fresh fruits and vegetables and the substitution of margarine for butter are the chief faults in the diets of goitrous children in certain districts.

It is more than probable that under present conditions of life a large proportion of the population lives on a diet which predisposes to a chronic state of hypovitaminosis. This is particularly the case with those who are near the lowest economic level at which satisfactory growth and health can be maintained. This universal shortage may account for numerous conditions of indefinite chronic ill-health, and intestinal derangements with accompanying toxæmias. But knowledge of nutrition and dietary requirements is far enough advanced to enable a well-balanced diet to be designed.

Ever since the introduction of modern methods of production, necessitating revolutionary changes in the dietary, the value of cod-liver oil as one of the richest sources of the dietary principles, vitamins A and D, has long been fully recognized. Malt Extract, which contains the B vitamins, has also been accepted as an extra dietary source of great value. Thus the difficulties of thoroughly re-building the diet and safeguarding the vitamin content are no longer a matter of concern, and the problem of adding a supply of the B vitamins to the diet, in addition to vitamins A and D, is simplified by prescribing 'Kepler' Cod Liver Oil with Malt Extract.

SPIRONINE

(SYN. ELIXIR ANTI-ASTHMATICUM)

SPIRONINE is a stable elixir each fluid drachm of which contains 3 grains of di-iodo-caffeine hydriodide together with the soluble constituents of 7½ grains of coffee.

In the compounding of the elixir a medium has been selected which appears to possess remarkable power to enhance the therapeutic value of the iodo-caffeine by increasing its rate of absorption into the system.

The elixir is readily tolerated and is perfectly harmless.

The value of iodine, in suitable organic combination, in asthmatic conditions (and in bronchial affections generally) is a matter of common knowledge.

On the other hand, caffeine is known to exert a specific action on muscle tissue, whether it be striped, plain, or cardiac muscle. This alkaloid possesses also well-known properties as a diuretic and, in addition, it serves as an agent for the stimulation of the respiratory centre.

The combination of these two valuable drugs as exhibited in Spironine produces a remarkably beneficial effect in dyspnoic conditions, and for this purpose it finds a wide sphere of usefulness in general practice in those conditions in which an anti-spasmodic is indicated.

IN ASTHMA

The principal use for Spironine in general practice is for the relief of asthma during the intermittent paroxysms that usually accompany the feeling of impending suffocation. It is well known that these distressing disturbances are likely to lead ultimately to the development of permanent damage to the lungs and heart; the administration of Spironine immediately the respiratory spasms appear modifies the chances of subsequent cardiac damage.

It is not claimed for Spironine that it is in any sense a cure for asthma, but it is claimed that the distressing respiratory and cardiac symptoms to which asthmatic subjects are prone respond promptly to treatment with this product. It is recommended for administration at the onset of an attack; its effect is immediate, the paroxysmal expiratory dyspnoea being relieved instantly, and such after-effects as emphysema are prevented.

AS A CARDIAC STIMULANT

In addition to its use in the treatment of asthma and its complications Spironine is of value in general practice as a cardiac stimulant, and it has been prescribed with considerable success in cases of weak heart following influenza, diphtheria and other serious illnesses.

In chronic conditions Spironine is best administered before meals two or three times a day, but it may be administered at any time during an acute attack of asthma spasms. The dose is one fluid drachm; this may be taken in a little water, or in milk if preferred.

It is issued in bottles of approximately 2½ and 5 fluid ounces, respectively, and in larger bottles for dispensary purposes.

'TANNAFAX' TANNIC ACID JELLY

THE inconvenience of preparing fresh solutions of tannic acid, and the deterioration of the solution when stored have limited its employment as a first-aid treatment for burns.

The precipitation of protein by tannic acid and subsequent formation of a firm coagulum are prevented by the application of olive oil and grease, the removal of which is necessary before solutions of tannic acid can be effective.

This unnecessary and harmful delay may be avoided by the use of 'Tannafax' tannic acid jelly. The product is prepared by Burroughs Wellcome & Co. It

is non-oily and non-greasy and has a water-soluble antiseptic base that can be easily bathed off when medical treatment demands the removal of dead tissues.

'Tannafax' tannic acid jelly is issued in tubes of two sizes and should prove of value both as a first-aid application and in general routine treatment.

THE BLOODLESS PHLEBOTOMIST

We have just received an advance copy of the most recent number of *The Bloodless Phlebotomist*. This little journal published by the Denver Chemical Manufacturing Company of New York contains interesting articles written by physicians from many different countries, and while the purpose of the publication is to acquaint its medical readers with Anti-phlogistine, physicians will find a number of items and illustrations which will excite their curiosity and interest—altogether, the little journal is well worth reading and we note that 1,260,000 copies are printed in nine languages and distributed to every doctor in the world with a known address, excepting in the countries of Russia, Lithuania, and Bulgaria.

If you do not receive a copy write to the Denver Chemical Manufacturing Company, New York, who will place your name on their list. The journal will be supplied you free of all charges.

MESSRS. COW AND GATE'S MEDICAL BULLETIN

The attention of the medical profession is drawn to this interesting monthly publication issued by the Cow and Gate Medical and Research Laboratories. It contains useful summaries of and selections from recent reports and pronouncements on infant feeding questions and dietetic research; bacteriological investigations of milk supplies and milk production in general are subjects also reported on and discussed at some length.

The *Bulletin* is a very convenient and well arranged summary for the doctor who is interested in these questions but has not sufficient time to collect or extract his own material. Copies of the *Bulletin* will willingly be provided on application to Cow and Gate, Ltd., Medical and Research Department, Guildford.

LACTOGEN

LACTOGEN represents a full-cream dried milk, modified by the addition of pure carbohydrate in order to rectify the deficiency natural to cows' milk. Behind the product stands the world-wide reputation of the Nestlé Company as manufacturers of milk products for more than fifty years.

The factories are supplied with milk from cows grazing in some of the world's richest pastures, a factor having an important bearing on the vitamin content of the milk. The supplies received by the Nestlé factories may therefore be regarded as ideal in this respect.

As fresh milk varies considerably in composition—even from day to day—each batch allocated for the preparation of Lactogen is rapidly analysed. Cows' milk always contains much less carbohydrate than human milk, and this deficiency is corrected by the necessary addition. Similarly, the butter-fat is adjusted to a definite ratio so that the composition, after drying, may be strictly uniform.

The milk is then pasteurized at 145°, after which it is passed through the various processes which are especially designed to produce a dried milk containing the full nutritive elements and the vitamins that were present in the original fluid milk.

Although modern research has demonstrated that earlier fears concerning the destruction of vitamins in

dried milk were largely unfounded, the greatest care is taken in the preparation of Lactogen to preclude any such possibility; the actual process of drying, in fact, occupying but a few seconds. However, to guard against any possible deficiency of the antiscorbutic factor, it is advised that a suitable fruit juice be given daily. This provides a safeguard which is to be recommended even when breast feeding is followed.

Recommendations for infant feeding are printed on the tins and this feeding table has received the approval of eminent infants' specialists. This is only intended, however, as an indication of the nutritive needs of the average child. It may require to be varied according to body-weight, calorific requirements, etc., but from the composition data provided it is a simple matter to modify the feeds according to the needs of any particular case.

INSULIN PRICES REDUCED

Burroughs Wellcome and Co. have announced a reduction in prices of 'Wellcome' brand insulin, which are now as follows:—

'Wellcome' brand insulin, 20 units per c.c.m., 5 c.c.m. phials, Re. 1-7 each net; 20 units per c.c.m., 10 c.c.m. phials, Rs. 2-14 each net; 40 units per c.c.m., 5 c.c.m. phials, Rs. 2-14 each net. The price of 'Tabloid' hypodermic insulin hydrochloride (10 units) has also been reduced. Cartons containing 10 products in one tube are quoted at Re. 1-7 per tube net. These are Bombay net prices to the medical profession.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

CONGENITAL SYPHILIS

By R. V. RAJAM, M.B., M.S. (Mad.), M.R.C.P. (Edin.)
Venereal Specialist, General Hospital, Madras

It is usually supposed that, in India, most of the infants born of syphilitic parents are either premature or stillborn, or die very soon after birth, and that consequently congenital syphilis is not very much in evidence. Nevertheless in the venereal department of the General Hospital, Madras, a fairly large number of cases of congenital syphilis were examined and treated during the years 1932 and 1933. This study comprises 163 cases of congenital syphilis.

Sex incidence

Age when first seen		Males	Females	Totals
Under 2 years of age.	69	43	49	92
Between 2 and 5 years.	23			
Between 5 and 15 years.	44			
Between 15 and 30 years.	27	40	31	71
	TOTALS	83	80	163

The youngest patient was two months old and the oldest thirty years; 98 per cent of the patients were Hindus. It will be seen from the figures of age and sex incidence that nearly 44 per cent of the cases were of the adolescent or later-childhood variety, and that the males were in excess over the females. It is usually thought that the female of the human species is better able to withstand and survive the invasion of the *Spirochæta pallida* during intra-uterine life, but the large number of adolescent male syphilitics does not confirm this view. It is possible that a greater number of male children die of the effects of syphilis both during intra-uterine life and immediately after birth, but once they manage to be born alive they seem to survive and grow up to adolescence better than the female.

Diagnosis.—In all the cases the diagnosis of congenital syphilis was made either on the clinical findings, or on the serological reaction of the child, mother and father. It was not found possible to get blood samples of all the children examined for the Wassermann reaction. The difficulty of venepuncture, combined with the fear and objection of the mothers to the operation on the first day of examination, prevented us from carrying out the blood test in a number of cases, especially as we wanted to

encourage the regular and systematic attendance of these children for treatment.

The following table shows how the 163 cases were diagnosed:—

Evidence on which diagnosis was made	Number of cases
Clinical findings and positive Wassermann reaction of the children.	68
Clinical findings, but with a negative Wassermann reaction.	15
Clinical findings only, no blood test performed.	60
Suspicious signs in the children with a characteristic maternal history, evidence of past or present disease in the parents, or positive serological reaction of the parents.	20

Clinical manifestations.—The clinical manifestations may be divided into those of early congenital syphilis, and those of tardive or delayed congenital syphilis. The following table gives the clinical manifestations and the number of cases in which they were observed:—

EARLY CONGENITAL SYPHILIS		DELAYED OR TARDIVE CONGENITAL SYPHILIS	
	Cases		Cases
Marasmus ..	15	Late skin lesions ..	20
Skin lesions ..	59	Pigmentary syphilides ..	7
Condyloma, anus ..	36	Radiating scars, mouth ..	6
Snuffles ..	9	Condyloma, anus ..	9

		Mental backwardness ..	8
		Deafness ..	2
		Myelitis ..	2
		Undersized with infantile sexual organs ..	1
		Past iritis with irregular pupils ..	1

MANIFESTATIONS OF EARLY CONGENITAL SYPHILIS

Marasmus.—A markedly marasmic condition was seen only in a minority of cases. In all of these there were other active lesions on which the diagnosis was based. The majority of infants were well nourished and plump, so that mere wasting or malnutrition has no diagnostic significance.

Early skin lesions.—These were the commonest in infants under one year. The lesions were rarely generalized but had a predilection for the ano-genital region, the area around the mouth, the palms, and the soles. The scaly maculopapule was the constant type. Three cases of pemphigoid syphilides were seen in the series.

Early mucous membrane and muco-cutaneous lesions.—Condylomata of the anus were the commonest lesions and were seen not only in infants but in older children up to the age of 10 years. Another peculiarity we noticed in our cases was that the condyloma is the only one lesion which has a tendency to relapse repeatedly during the first 10 years of a child's life. There was one case of multiple vegetative hypertrophic ulcerating syphilides all round the mouth in an infant one year old (*vide* figure 1).

Parrot's nodes.—These varied from well-marked swelling of the frontal and parietal bones to slight bossing and prominence. In more

periostitis and epiphysitis. The cases with epiphysitis were infants under six months. The affected bones were the humerus and femur. There was one case of severe multiple periostitis

Fig. 1.—Case of multiple vegetative hypertrophic ulcerating syphilides round the mouth.

than half the number of cases the bossing was observed in the frontal bones only (*vide* figure 2).

Sunken bridge of nose.—In no cases of early congenital syphilis in which this deformity was observed was there any evidence of destructive osteitis of the nasal bones or septum of the nose. This deformity is probably the result of arrested development or falling in of the bridge due to the negative pressure induced in the nasal chambers by obstructive rhinitis. There was not only a sinking or flattening of the nasal bridge, but also a tendency to flaring outwards of the alæ nasi.

Early bone lesions.—There were three cases, two of epiphysitis and one of multiple

Fig. 2.—Bossing of the frontal bones.

and epiphysitis involving all the long bones of the body in a child one year four months old (case III and figure 3). In all these three cases there were no cutaneous or mucous membrane lesions.

Enlargement of the spleen and liver.—The enlargement of the spleen and liver was observed only in a small number of cases and in all they were associated with other signs of congenital syphilis.

Lymphadenopathy.—In seven cases painless enlargement of almost all the lymphatic glands in the body was the only evidence additional to the serological reaction and family history.

Secondary anaemia.—There was one case of secondary anaemia, a child three and a half years old whose family history was suspicious and who had enlargement of the spleen, a suggestive facies, and a positive Wassermann reaction.

MANIFESTATIONS OF TARDIVE CONGENITAL SYPHILIS

Late skin lesions.—These were mostly ulcerative, gummatous, or nodulo-cutaneous lesions affecting the legs, the forearms, and the sternal regions.

Pigmentary syphilides.—Pigmentary syphilides were the only evidence in six of the seven cases in which they were observed. They chiefly affected the palms of the hands and the soles

Fig. 3.—Case of severe multiple periostitis and epiphysitis.

of the feet. In all these cases the question of acquired infection was ruled out. They were all under 15 years of age with a positive Wassermann reaction and bad maternal history. In one case, a boy aged seven, the condition was associated with Hutchinson's teeth and radiating scars of the mouth.

Destructive lesions of the palate and nose.—Destructive lesions of the palate and nose include perforation of the palate and septum of the nose, destructive ulceration and scarring of the alæ nasi, pillars of the fauces and soft palate. The youngest patient in whom a perforation was seen was two and a half years of age.

Facies.—The square head, the bossy forehead, the sunken bridge of the nose with increased distance between the eyes and a certain sleepiness or tiredness of look, these constitute the

facies of congenital syphilis. To this may be added, dental deformities and corneal opacities in certain cases.

Hutchinson's teeth.—Two types were seen; one was the typical Hutchinson's incisors with bulging sides, narrow crowns with a notch at the free border; the other type was peg-shaped with considerable distance between contiguous teeth and an antero-posterior thickening.

Fournier's molars.—Only in one case was this associated with Hutchinson's teeth; in the three others, the molars were the only deformity.

Eye lesions.—In all the cases but one there were only residual nebulae of the cornea, the result of past interstitial keratitis; all were females. The youngest was eight years and the oldest was 25. There was one case of a male aged 16 with irregular fixed pupils, the result of past iritis; he showed other evidence of congenital syphilis and had a positive Wassermann reaction.

Skeletal lesions.—Bones. The sabre deformity of the tibia was the commonest bone affection observed in cases of tardive congenital syphilis. The sabre deformity varied from slight anterior bowing to excessive bending. More important than the anterior curvature was the well-marked thickening of the bone, either diffuse, or localized to the centre of the lower third of the bone. The condition was invariably bilateral and marked degrees of it were associated with flat feet. The cases with gummatous osteomyelitis of the femur had also synovitis of the adjacent knee joint. There were four cases of osteoperiostitis affecting the other bones, humerus, radius, clavicle and fibula.

Joints. Four were cases of chronic hydrops affecting the knee joints. In all but one the affection was bilateral. X-rays showed no abnormality in the joints or bones. Two were cases of multiple osteo-arthritis with marked articular changes and periosteal new bone formation of the bones (case VIII).

Mental backwardness.—The patients were mostly males with ages varying from 6 to 20. The defect was slight, not amounting to feeble-mindedness or idiocy, except in one patient who was a definite idiot with a simian physiognomy, gummatous ulcers of the leg and sabre deformity of the tibia.

Myelitis.—One was a boy and the other a girl. They had a positive Wassermann reaction with other stigmata of congenital syphilis (case VII).

Illustrative cases

I. Male infant, 5 months old; third and last child of the parents.

Clinical condition. Marasmic, maculopapular and scaly eruptions on the trunk and the limbs; indurated ulcer of the umbilicus; ulceration of circum-oral region buttocks and anus; marked alopecia of the scalp. Blood test not available.

Mother. Clinical condition: Pregnancy three. First was a premature birth, and second died two months after birth. Involuting papular syphilides on the trunk and limbs.

Note.—The indurated ulcer at the navel of the infant with universal cutaneous eruptions and the active lesions in the mother suggested post-natally acquired infection, but the maternal history was very suggestive of congenital infection. This child did well with treatment.

Fig. 4.—Case III, male, aged 16 months, showing periostitis and epiphysitis.

II. Male child, A, aged 3 years; the second child of the parents.

Clinical condition. An indurated erosive chancre of left lower eyelid; left submaxillary glands enlarged, hard and painless; diffuse maculopapular syphilides all over trunk and limbs; no evidence of congenital lues. Blood Wassermann strongly positive.

Male infant, B, seven months old, the brother of A, and the fourth child of his parents.

Clinical condition. Well nourished and plump; square head and olympic forehead; bridge of the nose sunken; scaly and pustular syphilides on the buttocks, palms, and soles. Blood Wassermann strongly positive.

Mother of A and B, aged 20 years. Four pregnancies; first child is alive and well; third was stillborn. Extensive condylomata of the labia, perineum and anus. Blood Wassermann strongly positive.

Father, aged 30; history of chancre after the second child (A) was born. A few erosive papular syphilides on the inner aspect of prepuce and on the mucous membrane of the lips and palate. The patient reported that he had been getting these sores repeatedly.

Note.—In this group of cases the second child (A) must have been infected by contact with the parents. Hence the chancre of the eyelid and the diffuse cutaneous lesions. The absence of signs of congenital lues is indicative of acquired infection. The father's history also supports this. The fourth child (B) is a definite congenital syphilitic and the stillbirth between the second and fourth child is indicative of antecedent infection in the parents, before the fourth child was born.

III. Male child, aged 1 year 4 months; the first and only child of its parents born after 18 years of married life.

Clinical condition. Thin, wasted and under-developed for its age; bossy forehead, and sunken bridge to the nose; bluish sclerotics; multiple tender swellings of almost all the bones of the limbs, periostitis and epiphysitis (*vide* figure 4). Blood test not available.

Mother. No clinical evidence of syphilis. Blood Wassermann strongly positive.

Father. Denies any history of syphilis. No clinical evidence. Blood Wassermann positive.

Child did very well with treatment.

IV. Female child, M, aged 1½ years; sixth and last child of its parents.

Clinical condition. Annular syphilides, face and neck; depressed bridge of the nose. Blood test not available.

Female child, N, aged 9 years, sister of M, and the first child of the parents.

Clinical condition. Sunken bridge of the nose; Hutchinson's teeth; periostitis of tibia. Blood Wassermann positive.

Mother of M and N, aged 25 years; six pregnancies of which four were miscarriages. No clinical evidence of syphilis. Blood Wassermann strongly positive.

V. Female, child X, age 7; second child of its parents.

Clinical condition. Faeies suggestive of congenital syphilis, radiating scars round mouth, bossy forehead, and sunken bridge to nose; undersized for its age. Blood Wassermann strongly positive.

Female child, Y, age 1½ years; sister of X and last child of its parents.

Clinical condition. Snuffles; sunken bridge to nose; enlargement of the spleen; condyloma at anus. Blood result not available.

Mother of X and Y, age 25; pregnancies seven; only two children, X and Y, alive; two stillbirths; the other three died soon after birth. No clinical evidence of syphilis. Blood Wassermann strongly positive.

VI. Female child, aged 8; fourth and last child of its parents; was attending for chronic otitis.

Clinical condition. Intelligence below average; undersized for its age; slightly deaf in both ears; multiple patches of leucoma right cornea (history of eye trouble three years ago); left upper incisor is very

suggestive of Hutchinson's sign. Blood Wassermann strongly positive.

Mother, age 35, four pregnancies; first three children died soon after birth. No clinical evidence of syphilis. Blood Wassermann strongly positive.

VII. Male, aged 10, no family history could be obtained.

Clinical condition. Patient extremely emaciated; old man appearance; bossy forehead; upper incisors absent; Fournier's molars; multiple nebulae both cornea; pigmentation and keratoderma soles of both feet; flaccid paralysis of both lower extremities with sensory loss up to the umbilicus; incontinence of urine and faeces; large trophic ulcers sacral both trochanteric regions and both heels; mentally backward. Blood Wassermann strongly positive.

Fig. 5.—Case IX. Hutchinson's teeth.

Note.—A case of neglected myelitis in a congenital syphilitic

VIII. Male, aged 12 years; an orphan and the only surviving member of a family of 4 children.

Clinical condition. Multiple gummatous punched-out ulcers on both legs; multiple osteo-arthritis of left elbow and both knee joints—duration six months. X-ray showed characteristic changes of osteo-arthritis. Blood Wassermann strongly positive.

IX. Male child, aged 8; first child of his father by the second wife.

Clinical condition. Pigmentation of alae nasi; radiating scars round the mouth; peg-shaped Hutchinson's incisors (*vide* figure 5); leuco-melano-dermia of both palms of the hands; intelligence above the average for his age. Blood Wassermann strongly positive. Both the

father and the mother have the same leuco-melanodermic condition of the palms with blood Wassermann strongly positive.

This boy has been attending regularly and has finished three courses of arsenic and bismuth. His Wassermann reaction is still strongly positive; his cerebrospinal fluid is normal; the condition of his palms for which he came to the hospital is very slow to improve.

X. Male, aged 13; was being treated for kala-azar; family history not available.

Clinical condition. Patient emaciated and anæmic; marked enlargement of the spleen and liver; slight ascites, typical Hutchinson's teeth and mulberry molars; sabre deformity of both tibiae; pigmentation of palms and soles. Blood Wassermann strongly positive.

XI. Male, aged 14; no family history could be obtained.

Clinical condition. Boy extremely emaciated; suspicious facies; extensive nodulo-cutaneous ulceration and scarring of the right forearm and hand with flexion contracture of the right elbow and elephantoid clubbed contracted fingers and hands (*vide* figure 6). Similar but limited ulceration and scarring of the left elbow region. X-ray showed disorganization of the phalangeal bones of the little finger with considerable rarefaction of the other bones of the hand, wrist and forearm on the right side (*vide* figure 7). Such an affection of

so remarkably that he put on nearly 20 pounds weight in four months. An amputation was performed on the deformed and functionally-useless right forearm and hand.

XII. Female, aged 16; unmarried; second child of her mother.

Figs. 6 and 7.—Case XI.

the bones in syphilis seemed unusual. The patient had also osteosclerosis of the lower half of right femur. Blood Wassermann was strongly positive. With vigorous anti-syphilitic treatment the ulceration healed up completely and the patient's general condition improved

Clinical condition. Came in with perforation of the soft palate, no other evidence of congenital syphilis; a history of cutaneous eruptions in childhood and eye-trouble in her tenth year was volunteered. Blood Wassermann strongly positive.

Mother. Nine pregnancies of which two were still-births and three children died within a few days of

XIII. Male, aged 20; no family history could be obtained.

Figs. 8 and 9.—Case XV.

birth; the other children are well. Mother's blood Wassermann was strongly positive.

Clinical condition. Typical facies, square head, olympic forehead, flattened bridge of the nose with

deformed ala nasi, radiating scars round the mouth; patient considerably undersized for his age; sabre deformity of the right tibia; intelligence much below average; penis and scrotum infantile; has a shrill high-pitched voice. Blood Wassermann strongly positive.

Note.—In this case there seems to be a profound effect on the internal secretions and growth in addition to the stigmata.

XIV. Female child, C, aged 3 years; the first child of its parents.

Clinical condition. Bossy forehead, and sunken bridge to nose. No other evidence of congenital lues. Blood Wassermann strongly positive.

Male child, D, age 1½ years; the brother of C and the second child of his parents.

Clinical condition. Square head, bossy forehead, and markedly depressed bridge to nose; no other evidence of congenital lues. Blood Wassermann negative.

Mother of C and D, aged 23, is now pregnant five months. No history or evidence of syphilis. Blood Wassermann negative, even after provocation.

Father of C and D, aged 24; no history or clinical evidence of syphilis, either acquired or congenital. Blood Wassermann strongly positive.

Father's mother, age 54; pregnancies 16 of which the only surviving member is the father of C and D; she had 8 stillbirths and 7 children died soon after birth. No clinical evidence except the complaint of a boring pain in the right thigh. Doubtful osteosclerosis of right femur. Her blood Wassermann is strongly positive.

Note.—The clinical condition of the two children with a positive Wassermann in one, the absence of clinical or serological evidence of syphilis in the mother, the positive Wassermann reaction of the father in the absence of history or evidence of acquired infection, the bad obstetrical history of the grandmother with a positive Wassermann reaction are the peculiarities in this group of cases and suggestive of third generation syphilis.

XV. Female, aged 25, unmarried; no family history could be obtained.

Clinical examination. Patient undersized for her age; mentally backward; typical facies, markedly sunken bridge to the nose; active interstitial keratitis eyes; Hutchinson's incisors; breaking down gumma of the upper end of the sternum; marked thickening and anterior curvature of tibiae with multiple scars over it. Pigmented palms. Blood Wassermann strongly positive (*vide* figures 8 and 9).

Note.—This is a case with active lesions and typical stigmata of congenital syphilis at such an advanced age. The curvature of the tibia is rather extreme and suggests a rachitic element also. The active lesions responded well to treatment.

XVI. Female, aged 30, married; four pregnancies, the first three children died soon after birth, the fourth child, 2 years old, has flaccid paralysis of both legs with atrophy.

Clinical condition. Pigmented palms; nebulae both cornea; history of having had interstitial keratitis when she was ten years old with recurrence of the trouble frequently for which she had received injections; no other evidence of congenital lues. Blood Wassermann strongly positive.

The question in this case is whether she was a congenital syphilitic and whether her bad obstetrical history was due to the connubially-acquired disease. It is suggestive, but not conclusive in the absence of information regarding the husband's status. Her child with flaccid paralysis of the legs has no evidence of congenital lues and the blood Wassermann is negative.

XVII. Male, Anglo-Indian, aged 11 years, the eldest child of his parents; a prematured child, seven months, well until now.

Clinical condition. Slight bossiness of the forehead; chronic hydrops of the left knee of 8 months' duration; the knee trouble started after some trivial injury; it was treated with plaster of Paris with no benefit; x-ray

showed no abnormality in the bones of the joints. Blood Wassermann strongly positive. Was put on anti-syphilitic treatment and the joint condition responded rapidly.

Mother of the patient, age 27, is the eighth in a family of 10 members, of which only five are alive. The rest died soon after birth. Her younger brother, ninth in the family, has been a paralytic for 13 years; *see* history below. She was married in her 15th year; has had seven pregnancies; the fifth and sixth children died young.

Well developed and healthy looking; no other evidence of congenital syphilis except Hutchinson's incisors. Wassermann reaction negative. History of husband not available.

Maternal uncle of patient, aged 25 years; in his twelfth year he suffered from paralysis of both legs, and loss of vision both eyes. His blood Wassermann then was strongly positive. He was treated with mercury injections and recovered from the attack; had another attack of complete paralysis in his 21st year, i.e., 4 years ago, with sphincter trouble and sensory loss; had a series of novarsenobillon injections in one of the local hospitals and he partially recovered.

Now, he has slight flaring of the nostrils; Hutchinson's incisors with a notch at the free margin; no other stigmata of congenital lues; spastic gait; walks with a stick; tendon jerks markedly exaggerated; no loss of sensation and no sphincter trouble; intelligence above average. Blood Wassermann negative, even after provocation.

Note.—The infection in the boy is suggestive of third generation syphilis for the following reasons; the bad obstetrical history of the mother's parents, the solitary stigmata in the mother (Hutchinson's teeth), the history and clinical condition of the uncle. In both the mother and the uncle, the blood Wassermann was negative; this is not surprising in view of the long duration of infection. Of course a serious defect in the evidence for third generation syphilis is the absence of any information regarding the status of the father of the boy.

TREATMENT

The combined therapy with arsenic and bismuth is the routine treatment employed. In infants and children with poor veins the intramuscular injection of one of the sulfarsenobenzenes was the route of choice; in the others, neosalvarsan intravenously was given. In marasmic, very emaciated infants, dribble doses ranging from 0.0075 to 0.025 gramme were given on alternate days, and when the infant's general condition improved higher doses were employed. It is remarkable how children and adolescents stand continued arsenic and bismuth therapy without showing any signs of intolerance. Large doses are borne without any untoward results. The doses employed in the department are as follows:—

	Weekly dose of sulfarsenobenzene or neosalvarsan	Weekly dose of bismuth metal
Under 1 year ..	0.05 to 0.075 gramme.	0.05 gramme
Children between 2 and 5.	0.075 to 0.1 gramme.	0.05 to 0.075 gramme.
Children between 5 and 15.	0.1 to 0.2 gramme	0.1 to 0.15 gramme
Above 15 years	0.2 to 0.3 gramme	0.1 to 0.2 gramme

THE TOXIC EFFECTS OF EMETINE

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

School of Tropical Medicine, Calcutta

ALTHOUGH emetine is a drug extensively used in this country, the toxic effects produced by it are not always fully appreciated by the profession. During the last 12 years the author has treated a large number of cases of amœbiasis with emetine in the Carmichael Hospital for Tropical Diseases, and has met with untoward effects in spite of all precautions. Apart from these, many patients suffering from emetine poisoning have come to the hospital for relief of their symptoms. In this paper it is proposed to deal briefly with various toxic symptoms produced by this alkaloid, many of which could be avoided if it were realized that emetine is a

(Continued from previous page)

The doses employed above are higher than those usually recommended, but we have had no ill results. We tried stovarsol tablets by the mouth in a number of infants who were thought too ill to stand injections, but our results were not encouraging.

PROGNOSIS

It is much easier to prevent congenital syphilis than to cure it. Even in the early stages of the disease one has got to deal with a firmly entrenched infection. It is possible to cure the disease within the first six months of the child's life by intensive and prolonged treatment. In the later years of childhood and adolescence, treatment may affect the clinical quiescence of the disease. In the later childhood and adolescent cases, the Wassermann reaction remains unaffected by treatment though there is a great improvement in the general condition.

CONCLUSION

There is a good deal of congenital syphilis in this part of the country which is not surprising considering the high incidence of acquired infection in the population and the imperfect treatment, or the absence of any treatment at all, of the acquired infection. The large number of untreated adolescent congenital syphilitics in our series, mostly of the male sex, is a striking feature. The problem of third generation syphilis requires more investigation by all the workers who treat syphilis. We have seen two cases in which the possibility of the infection being transmitted to the third generation, one through the mother and the other through the father, is suggested.

I am indebted to Dr. Mathuranayagam, the lady in charge of the female side of the department, who was of considerable help in preparing this article. My thanks are also due to the director and staff of the x-ray institute for the illustrations and x-rays.

potent drug having a powerful action on the vital organs, and that it should be given with great care.

Toxic effects in animals

That emetine is a toxic drug has been amply shown by experiments on animals. With large doses, the changes produced in the tissues are of an acute nature, and immediate death within 24 hours may be produced with one single large dose. Doses of 0.05 to 0.075 gramme per kilogramme in dogs, and 0.02 to 0.15 gramme per kilogramme in rabbits, guinea-pigs, rats, etc., are rapidly fatal. With medium doses the pathological changes are more marked, more time being allowed for their production. With smaller doses it takes longer to produce the same pathological changes, indicating a cumulative action of the drug. There is probably no threshold of safety when the drug is administered continuously.

It should be realized that emetine attacks all tissues and therefore is a general protoplasmic poison; changes in the kidney, liver, heart and skeletal muscles are identical, all showing hyperæmia, cloudy swelling and degeneration of the cells.

Cardiovascular effects.—On the heart of both cold-blooded and warm-blooded animals, emetine has a markedly toxic effect. It depresses the excitability and conductivity of the myocardium and produces slowing and dilatation of this organ resembling that produced by chloroform. The heart becomes irregular, auricular and ventricular dissociation may be produced, and death may occur from ventricular fibrillation, the heart stopping in diastole. In animals intravenous injections of large doses produce a marked fall of blood pressure; after small doses the pressure soon regains its normal level. The fall of pressure is due partly to the direct toxic action of the drug on the heart, but vasomotor paralysis is an important factor especially after large doses. In man there is an appreciable fall of blood pressure, to the extent of about 20 millimetres of mercury, after an intravenous injection or after a number of doses by the other routes. The characteristic rapid and compressible emetine pulse and cardiac irregularities of various types are seen after a series of injections of this alkaloid. The isolated heart is slowed and weakened by both emetine and cephaline, and it finally stops in diastole.

Non-toxic doses, while they lower the carotid pressure in animals, produce a rise in the pressure both in the pulmonary artery and vein. Larger doses dilate the pulmonary vessels. The coagulation time of the blood is not altered though some think it is delayed. Emetine is toxic to the capillary endothelium producing petechial hæmorrhages; local application of the alkaloid gives rise to capillary hæmorrhage.

Effects on the nervous system.—The alkaloid has a powerful effect on the nervous system. In the frog, emetine produces a slowly advancing

No general disturbances or gastro-intestinal symptoms are produced in man when a therapeutic dose is given by injection; local reaction as a rule is small when the solution is neutral. Larger doses cause nausea, vomiting and diarrhoea. As much as 0.25 gramme has been given for a single dose without producing any other symptom except persistent nausea, but if a very large dose of emetine is given the patient may suddenly faint, and death may occur from paralysis of the heart. When repeated injections of small doses are given, there is persistent nausea and vomiting, diarrhoea, vertigo, extreme muscular weakness and expiratory dyspnoea; the pulse is at first slow and then rapid. Death results from exhaustion, gastro-enteritis or intercurrent inflammation of the lungs. It should be remembered that there may be wide differences

in the toxicity of various commercial samples of emetine on the market.

Clinical experience has fully established the fact that emetine is a cumulative poison in man. The dosage and the length of time during which it should be given have therefore to be very carefully considered. Formerly, untoward effects from its use were put down to the disease being treated and this accounts for such a diagnosis as post-dysenteric heart failure. Recent investigations have shown that undoubted cases of sudden failure of the heart have been produced by prolonged use of emetine. The depressing effect of the drug, when given in doses of one grain daily for some time, is very marked, the noticeable features making their appearance after the fourth to sixth injection, being the loss of appetite, nausea, vomiting, vague abdominal pains and diarrhoea due to gastro-intestinal irritation. Among the serious symptoms of poisoning are an increased pulse rate, listlessness and cardiac and mental depression. There may be general lassitude, disinclination to make an effort, weakness of the legs, tremors of muscles, globus hystericus, cardiac arrhythmia, low blood pressure and a feeling of faintness. General oedema, petechial hæmorrhages, purpuric skin rashes, hæmoptysis and signs of cerebral and pulmonary oedema may also be present. Albuminuria frequently occurs. Polyneuritis is common and in some cases difficulty in swallowing and a feeling of constriction about the throat and chest have been observed. Urticaria and large pruriginous plaques, persisting sometimes for a month after the last injection, have been known to occur even after a few injections of the alkaloid. A number of such patients have come to this hospital for treatment. Sudden collapse and death may supervene in some cases. Auscultation of the heart in emetine poisoning shows similarity of sounds, and a lack of the muscular element in the first sound. Cardiac stimulants should be used in such cases at the earliest possible moment when the signs of cumulative toxic effects have appeared. Degenerative changes were recorded by Bais (1921) in human beings after prolonged use of the drug. The author and his co-workers (1924) demonstrated that in rabbits marked histological changes of a degenerative type occur in the heart after emetine injections. These consist of cloudy swelling, disappearance of the transverse striations and atrophy and fibrosis of the muscle. Chopra and Sen have shown that degenerative changes may be produced in the myocardium after therapeutic doses of emetine which can be detected by electrocardiographic examination.

Emetine neuritis.—Neuritis of the lower extremities is one of the early symptoms and is manifested at first by weakness in the legs, difficulty in walking and interference with the normal reflexes. Usually there is no pain on pressure as the motor nerve fibres only are affected, but cases of painful neuritis have been observed. Wrist drop, ankle drop, and toe drop

may rarely be produced though we have not observed them in our series; hyperæsthesia of the soles of the feet, sluggish knee jerks, and loss of taste have been noticed in some patients. It is possible that difficulty in swallowing and the sensations about the throat and chest produced after emetine injections are due to involvement of the nerves supplying those parts; it has also been suggested that these effects may be due to changes in the nuclei in the medulla oblongata similar to those that have been observed in animals in the cells of the anterior horn of the spinal cord. In some individuals symptoms are produced after 8 or 9 grains of the alkaloid. Palsy may develop some considerable time after the cessation of treatment. Fibrotic changes have been observed in experimental animals after large doses of emetine and similar changes probably occur in man. Emetine has not been detected in the cerebrospinal fluid.

Emetine diarrhoea.—Emetine when given in considerable quantities produce diarrhoea. It has already been pointed out that in animals emetine may produce gastro-enteritis with hæmorrhages in the lymphatic glands, spleen, kidneys and thymus. These experimental animals die even though emetine is discontinued directly the symptoms appear. Diarrhoea which is the first sign of irritation of the gastro-intestinal tract was quite common in the old days, the rationale of ipecacuanha treatment being to push the remedy till profuse diarrhoea was produced and the stools became liquid and of a canary-yellow colour. After discontinuing the drug the stool assumed its normal consistency and to all intents and purposes the patient was considered cured. Low (1915) noticed that diarrhoea (occasionally with blood) occurred after hypodermic injections, but not so commonly as when ipecacuanha was given by the mouth. It is not unusual for the patient to get a slight attack of diarrhoea after the sixth injection. With the oral administration of emetine-bismuth-iodide, diarrhoea is frequently met with, and when mild this is considered to have a beneficial effect and is not a sign of intoxication. In addition to the specific action of the drug, the bowel is at the same time thoroughly washed out and this mechanical process is valuable, as is evident from the successful treatment of bacillary dysentery with saline purgatives.

Cautions and contra-indications.—Emetine is a protoplasmic poison acting equally on most of the tissues of the body, heart failure being the actual cause of death. In cases where the heart or kidney is affected, it is advisable to give as small doses as possible for the treatment of dysentery. In otherwise-healthy individuals the number of injections should be limited as far as possible to nine, and under no circumstances should more than one grain be given in 24 hours.

It should be remembered that emetine, if administered continuously, depresses the heart, but signs of cardiac depression improve when it is withdrawn. Caution is indicated in all cases

where the myocardium is damaged by other diseases, such as malaria (malignant form), influenza, and diphtheria. The patient should be confined to bed during the period of emetine treatment and an accurate record of the pulse rate should be kept. If this is definitely increased, or palpitations occur, the drug should be withheld till the heart resumes its normal rate. Under no circumstances should a course of emetine injections be given in ambulatory patients.

Convalescents who have received a course of emetine should be allowed to leave the bed very cautiously to allow the effects of the drug to pass off, and, if the pulse rate increases much, they should return to bed. The author has seen patients whose hearts were permanently strained for want of this precaution. It is necessary to emphasize at the risk of repetition that emetine is a powerful drug having a selective action on the heart muscle and that great care should therefore be taken when it is being used.

Emetine in pregnancy.—It has been suggested that emetine should be avoided in pregnancy as it may cause abortion. Some pharmacologists have stated that emetine increases the contractions of the uterus and have issued a warning against its use in pregnancy. On the other hand clinicians have given injections of emetine in advanced cases of pregnancy without untoward results. Recent investigations have shown that after a dose of one grain, assuming that the whole of the alkaloid is absorbed, the concentration of the drug in the blood cannot possibly be greater than 1 in 150,000 to 1 in 100,000. Such dilutions have little effect on the isolated uterus, and if there is any action at all, it is a tendency to relaxation. Acton and Chopra showed that abortion is more common in cases of bacillary dysentery and is produced by the bacterial toxins; they showed that the toxin of *B. dysenteriae* (*Shiga*) is a powerful ecboic. Emetine does not appear to be a causative factor in producing abortion and the coincidence of a miscarriage when injections are being given seems to be due to the toxins of the parasite rather than to the drug. Pregnancy is not therefore a contra-indication to the use of emetine. In menstruating women it is preferable to start the injections after the period is over, but in urgent cases treatment should not be deferred.

DIAGNOSIS AND TREATMENT OF SOME URINARY COMPLICATIONS IN GYNÆCOLOGY*

By W. C. SPACKMAN, M.B.B.S. (Lond.), F.R.C.S.E.,
M.C.O.G.

LIEUTENANT-COLONEL, I.M.S.

Professor of Midwifery and Gynæcology, Grant Medical College, Bombay

THERE is no need to stress the very close developmental connection between the urinary and generative systems. I have felt however that in our wards and theatres the clinical and pathological connection might receive more attention, not merely on account of its very great technical interest, but also because recognition and correction of injuries and disorders of the urinary organs can be of incalculable benefit to many of our patients.

It is not my intention in the present paper to deal systematically with the very wide field of urology as met with in our gynæcological and obstetrical wards, but rather to refer to a few cases and conditions in my own experience which have been of great interest to me and which I hope will similarly interest you.

Injuries to ureters

A review of recent literature both of urology and of gynæcology reveals a recognition that injuries to ureters occur more frequently than is often supposed, especially in the practice of gynæcological surgery. As an example, we perform a difficult hysterectomy for carcinoma or a broad ligament tumour; we have not perhaps been able satisfactorily to trace out the ureters to their entry into the base of the bladder and are a little doubtful in our minds as to whether in tying off the troublesome vessels of the broad and utero-sacral ligaments we have avoided the ureter; or in clearing the ureter from its bed we suspect we have denuded it so that its walls cannot resist the unfavourable contact with the raw and perhaps infected tissues left behind. In the days immediately following operation, we look fearfully for suppression of urine or for urinary leakage from the vagina; neither appears and we say 'no harm done'; but the patient has a very stormy convalescence and a lot of pain in one side, which probably ultimately settles down more or less, without our having formed any clear idea as to its origin. We have in fact tied off the ureter on that side accidentally without realizing it and the patient owes her recovery to the adequacy of her remaining kidney.

Whilst rare, this happens I believe more often than we realize. I have notes of one such case where I afterwards verified the injury by cystoscopy and of another case where we suspected it but proved it had not occurred.

* Being a paper read before the Tenth All-India Medical Conference, 1933 (Section of Gynæcology).

The recognition of this accident is quite easy by chromocystoscopy, which gives clearer and more precise information on this and many other urological conditions than excretion urography (with uroselectan for example) behind which so many gynæcologists shelter. It is only when the bladder walls are greatly distorted that it may not be possible to locate with the cystoscope the points of entry of the ureters into the bladder and to watch for the indigo-carminic, which we have caused to be injected into the patient's veins or muscles, to appear from them.

Having recognized by these or other means that a ureter has been ligated, we have three possible courses open to us :

1. We may re-operate to divide the ligature, an exceedingly difficult procedure indeed.
2. We may leave things as they are (if the other kidney appears adequate).
3. We may do a nephrostomy as a temporary or permanent expedient.

Which of these three courses we adopt will depend on the conditions present in the case in question; if by ill fortune both ureters have been tied and anuria results, a condition to be diagnosed by finding the absence of all secretion *via* the ureteric orifices (as seen by the cystoscope) associated with blockage at an appropriate distance to the passage of a ureteric catheter up each ureter in turn, a rapid bilateral nephrostomy will probably be the only means of saving the patient. There are great technical difficulties in finding and releasing the ligature which occludes the ureter, at a secondary operation.

Uretero-vaginal fistula.—This is practically always traumatic (*i.e.*, the result of operative trauma, sometimes unavoidable). It is characterized by a urinary discharge from the vault of the vagina whilst at the same time the bladder continues to fill and empty regularly under normal control. It is very important to distinguish this condition from two others, *viz.*, a very small vesico-vaginal fistula, and a weak sphincter. The three conditions are liable to be confused especially in an uneducated patient. In all three the vagina is wet whilst the filling and emptying of the bladder continues. The diagnosis of uretero-vaginal fistula can usually be made without difficulty by chromocystoscopy, when we see the indigo-carminic coming down one ureter and not the other. There is, however, a very useful and practical test, which I do not remember to have seen described and which we call the 'two swab test'. You put a dry cotton swab into the vault of the vagina and another one below it in the lower half of the vagina. Then put two ounces or so of methylene blue solution into the bladder which has been previously emptied by catheter. After waiting two or three hours the swabs are withdrawn and examined. If the upper one is blue the leak is from the bladder; if the lower one only, then it is a case of weak sphincter.

To distinguish a small vesico-vaginal fistula from a uretero-vaginal fistula, repeat the test twice, first as above and the second time after emptying the bladder give a dose of intravenous indigo-carminic. In uretero-vaginal fistula, the upper swab will be colourless the first time but coloured the second.

Uretero-vaginal fistulae cannot be cured by operation *per vaginam*. It is therefore essential not merely to diagnose them from vesico-vaginal fistula, but to decide for certain from which ureter the leak is taking place. This can only be done by a cystoscopic examination. It would be a great tragedy for a patient suffering from a fistula from the right ureter opening perhaps into the left vaginal vault to have the left kidney removed to cure it.

We had one case where there was spontaneous cure. The vaginal leak ceased and the ureter was found to be emptying normally into the bladder. In such a case, it is probable that the main continuity of the ureter has not been interrupted but a small lateral opening has been made. This is called an incomplete uretero-vaginal fistula and might afford a chance of cure by operation from below. Spontaneous closure occurs more often; this involves occlusion of the ureter by scar tissue and consequent destruction of the kidney function on that side.

We had two other cases of traumatic uretero-vaginal fistula, one following a Wertheim's hysterectomy and the other a vaginal hysterectomy for prolapse. The latter case we treated in the following way. We exposed the pelvic portion of the ureter extraperitoneally through a median hypogastric incision and re-implanted it into the bladder. The case was cured by this and the kidney on that side continued to function so long as the patient was under observation; as this was only a few weeks, we cannot say more. It is said that these cases often end in gradual loss of kidney function on the affected side.

In the second case, where we had operated for carcinoma of the cervix, I did not like to reopen the tissues in the above way, but preferred to do a nephrectomy after ascertaining that the other kidney function was normal. This gave a very satisfactory result to the great comfort of the patient.

Vesico-vaginal fistula.—The secret in successful operation in these cases is free mobilization of the bladder. Provided this can be accomplished, cure can be effected in nearly all cases. Perhaps on this side of India we see less severe cases than occur elsewhere, but we have very rarely failed to cure, though we occasionally have to operate a second time to complete the closure. I am convinced that wide dissection and free mobilization of the bladder are all-important. In recent years I have only seen one case where the only resort was rectal implantation of the ureters, and this we did

RELAPSING MALARIA

By D. MANSON, M.B., Ch.B. (Glas.), F.R.S.

Medical Officer, Jorhaut Tea Company, Limited, Cinnamara, Assam

CASES of obstinately relapsing malaria are of frequent occurrence in all parts of the tropics, and nowhere more so than in Assam where malaria constitutes one of the major problems which the medical profession is called upon to solve.

The treatment of relapsing malaria is very inadequately described in most of the standard textbooks on tropical diseases and the impression is generally conveyed that relapses should be dealt with in the same way as the original attack. Little attempt is made to discuss the part played by the patient in finally establishing a cure and the fact that malaria is a self-limiting disease is entirely ignored.

The following notes are descriptive of such a case and are presented because they illustrate one or two points which may possibly be of general interest.

The patient is an European lady, aged about 33 years, who has been resident in Assam for about 10 years.

The husband of the lady developed an attack of malignant tertian malaria on the 27th August, 1933, the blood films showing a fairly heavy infection. As former experience on several occasions had proved that when her husband contracted malaria she was almost certain to have a similar attack, she requested me to give her

(Continued from previous page)

after the technique of Green-Armytage and obtained a very successful result, verified some months after.

Pyelitis.—These cases often give most gratifying results to lavage treatment *via* the ureters with the ureteric catheter. We use a 5 per cent. solution of argyrol and it must be done without any anaesthesia to avoid over-distension of the kidney pelvis. It is first essential to exclude either renal calculus or renal tuberculosis as the cause of the pyelitis. In cases where urinary antiseptics fail, this form of treatment is most valuable. Here is an illustrative case, from the Motlibai Hospital:

Mrs. A. S., Hindu, aged 25, eighth pregnancy, seven months pregnant. Admitted on 27th October, 1933, for fever and cough for past three days.

Previous pregnancies normal, all children living, youngest aged 2 years.

On admission looked ill and wasted. Irregular fever, albumin and pus in her urine; culture revealed *B. coli*. Blood pressure 110/60; Widal negative.

No response to urinary antiseptics.

Therapeutic induction on 11th November, 1933. Fever fell to normal on 18th November and patient began to pick up. Became very ill again on 27th November. High irregular fever, rapid wasting, patient looked desperately ill; many pus cells in urine. No response to various urinary antiseptics. Kidney lavage (5 per cent argyrol) performed on 1st December. Temperature fell to normal next day, remained down and patient rapidly improved. Discharged in good condition on 17th December; very few pus cells in the urine.

some form of prophylactic treatment. It was therefore decided to try the efficacy of a course of atebtrin and plasmochin. The dose given was 0.1 gramme of atebtrin thrice daily for five consecutive days together with 0.01 gramme of plasmochin for the same period.

This treatment was commenced on the afternoon of 27th August and was completed on the morning of 1st September.

On 5th September, the patient complained of sickness, vomiting, and headache with slight rigor accompanied by a temperature of 100.8°F. Symptoms began about 8 a.m. and the temperature continued till 6 p.m. Blood films (thick and thin) were examined on the 5th morning and again in the evening of the same day but were negative, even after prolonged search.

Blood was again examined on the 6th and was still negative, although six slides in all were searched.

Although the symptoms were indicative of clinical malaria, no treatment was adopted in the absence of a definite finding in the films examined. Blood was examined on the 7th, 8th and 9th, but remained negative. On 25th of September, there was a mild recurrence of the same symptoms with temperature ranging from normal to 100.4°F. at midday.

17th October. The clinical symptoms of malaria again manifested themselves. Six blood films were examined on the 17th, and found negative. Blood was examined daily from 17th to the 21st.

21st October. Blood films showed malignant tertian malaria. Temperature 102°F. Patient was given 10 grains of quinine bishydrochloride intravenously and on the following day a course of atebtrin and plasmochin was started. Atebtrin was given in doses of 0.1 gramme thrice daily for 5 days and plasmochin in a dose of 0.02 gramme once daily on the 3rd, 4th, and 5th days, but not on the first two days after the onset. After completion of this treatment, nothing was given for 3 days and then a further two days treatment was exhibited, atebtrin, 0.1 gramme thrice daily and plasmochin 0.02 gramme once daily at bedtime being administered. Blood films were negative from the 24th, and were examined daily until the 31st, remaining negative during that period.

28th November. There was a recurrence of malarial symptoms on this date. Blood films showed malignant tertian rings on the thick film only. Treatment began with 10 grains of quinine bishydrochloride intramuscularly, followed by a course of quinine, commencing with 30 grains daily for 3 days and reducing to 20 grains on subsequent days. In all 280 grains of quinine were given between the 28th November and 12th December. Blood films were examined frequently until 13th December and remained negative during that time.

29th December. Slight malaise; temperature 99.8°F. with sickness. Blood showed malignant tertian. Malaria treatment was commenced with atebtrin 0.1 gramme twice daily for seven and a half days along with plasmochin 0.01 gramme twice daily on the 5th, 6th, and 7th days only. Blood was negative on 30th, and remained negative until the 5th January, 1934, when daily examination was discontinued.

9th January, 1934. Slight sickness, no fever. Blood film malignant tertian rings. Treatment—Atebtrin, 3 tablets only on 10th January.

11th January. Blood positive, malignant tertian treatment, 2 tablets atebtrin.

12th January. Blood negative, atebtrin stopped. From the 9th January, treatment was entirely guided by blood findings as it was evident that long and complete courses of atebtrin and plasmochin and of quinine were not effective in limiting the progress of the infection.

Blood films were examined daily and, if positive, one or two doses of atebtrin were given until the blood again became negative.

Blood films were positive on the 31st January, but the parasites disappeared from the peripheral blood after two doses of atebtrin of 0.1 gramme each. Blood films were examined daily until 18th February and

remained negative. The patient left India on home leave at the end of February and up to that time there had been no recurrence of malarial symptoms. She was instructed to limit treatment of any subsequent malarial symptoms to the minimum amount of atebirin which would give complete relief.

The patient's hæmoglobin was found to be 70 per cent (Tallqvist) on the 1st January, 1931, and a course of iron arsenate in ampoules of 1 c.cm. was started. One c.cm. was given daily for 3 weeks by the intramuscular route.

At the conclusion of treatment the hæmoglobin was found to be 85 per cent (Tallqvist).

In addition to the above, the patient was enjoined to rest as much as possible and to avoid fatigue as the fatigue factor contributes very largely to relapses.

The importance of these factors and the use of a suitable hæmatinic are essentials in symptomatic treatment.

Discussion

The first point of interest in this case is the failure of a five days' course of atebirin and plasmochin, exhibited in full curative dosages, to arrest the onset of typical clinical malaria within four days of the completion of treatment.

It is a moot point as to whether blood culture would have revealed the presence of malarial parasites in the peripheral blood as the slow elimination of atebirin might easily have interfered with the success of the culture. In any case, blood culture is merely a finer method of search than is afforded by thick films and is not likely to have shown a positive result in view of the number of thick films examined and the time spent on them.

The second point of interest is the failure of atebirin and plasmochin and of quinine to prevent relapses after very adequate courses. The atebirin course was varied in each different treatment with a view to finding a better mode of exhibition and, in the last course, was given in smaller doses over seven and a half days in order to allow for the establishment of natural immunity in the patient. The final course adopted, of limiting treatment according to blood findings, seemed to be the only reasonable method of attack in this case.

I should like to point out that re-infection can be eliminated in this case from 1st December onwards, as transmission of malaria in this part of Assam is then in abeyance. Gut and gland infections in *Anopheles minimus* which is the vector *par excellence* of malaria in Assam are extremely rare after 1st December. *A. minimus* will not feed when the minimum temperature falls regularly below 60 degrees F. These findings have been repeatedly verified, in the Surma valley by Ramsay (1930), and in the Brahmaputra valley by the writer (1931). The minimum temperatures in Assam fall regularly below 60 degrees F. about 20th to 24th November each year. It has further been established that wild *Anopheles minimus*, which normally feeds readily, will not partake of a blood meal in the laboratory after the fall in night temperatures to 60 degrees F.

The argument might be adduced that the attack of clinical malaria on 5th September should have been treated and that the subsequent relapses might thus have been eliminated. This is unlikely as atebirin must still have been present in the general circulation in considerable amount on that date, as complete excretion takes about two or three weeks. It seems most probable that a further exhibition of atebirin would not have led to cure at that time. The final course of treatment adopted agrees in principle with the method advocated by the Malaria Commission of the League of Nations (1933). Their report on malaria is a model of completeness and clearness.

The use of quinine with atebirin is not advised by the Commission, but, on what precise grounds, is not stated.

The necessity of limiting the infection as soon as a positive diagnosis is made seems to be of primary importance in gastric types of malaria, and the first consideration from the patient's point of view is the cessation of fever. Whilst the establishment of natural immunity is indicated as an essential part in the cure, the patient cannot be left for a few days untreated as suggested in the report of the Commission. In these circumstances, the preliminary use of quinine appears to be eminently indicated. Regarding the final symptomatic method of treatment, so far as my experience goes, I have found it better, in severe relapsing malarias, especially of the malignant type, to avoid excessive medication and to allow the patient to assert his own natural immunity, helped out by the judicious use of suitable drugs which will prevent the appearance of clinical symptoms. Extensive medication in these cases, in my experience, only leads to hæmoglobinuria and even to blackwater fever. In this opinion, I find that most old residents in Assam agree thoroughly. Malaria is a self-limiting disease and this rational mode of treatment commends itself.

It is necessary here to emphasize the need to watch the process of cure with extreme care and to be guided by regular blood findings. The need for rest, the avoidance of fatigue, and the use of suitable hæmatinics must also be stressed. Iron by injection has recently come under the ban that falls periodically on all modes of treatment in all diseases, but I have never found the patient fail to respond to injections of iron arsenate in this type of case.

Summary and conclusions

Atebin and plasmochin in full curative doses failed to prevent the onset of clinical malaria within four days.

Atebin and plasmochin in various doses and combinations failed to prevent relapse in this case. Quinine in large doses also failed to establish a cure.

NAGA SORE IN A TEA-ESTATE PRACTICE*

By A. K. GHOSE, L.M.F., L.T.M.

Medical Officer, Ambari Tea Estate, Carron Jalpaiguri

NAGA SORE is a disease that is responsible for the crippling of a large number of tea-garden coolies during the busiest season of the year; though there is no mortality from this disease, unless complicated with some other intercurrent disease, it disables more coolies for a longer time than malaria and hookworm disease taken together. Sometimes it occurs in epidemic form and affects a large percentage of the working coolies so that the work of the garden is seriously hampered.

Season of onset.—It invariably occurs during the monsoon months. Last year it began in the early part of May and attained its maximum in June and July. It began to diminish after the monsoon and has now entirely disappeared in December.

Sex.—Of 69 cases, 41 were men, 25 women, and 3 children; that is to say, both sexes are equally prone to this disease.

Age.—Only 3 cases occurred in children; the rest were among those doing outdoor work. Generally boys and girls above 10 years work in the garden.

Mode of onset.—It was always preceded by some injury, e.g., a cut, an abrasion, a leech-bite, or a thorn-prick, or by scabies. Sometimes the ulcer was formed very rapidly, say within a week, after the primary injury.

The part of the body affected.—It is very selective in its distribution; it was mainly found on the legs below the knees. In my series there was one instance of ulcer on the mamma of a woman and another on the forearm; in the rest it was situated below the knees. This selective distribution of the ulcer suggests soil infection.

Signs and symptoms.—At first there is nothing but a simple abrasion, in about a week or so

this assumes its characteristic appearance. It presents a punched-out appearance, and may be circular, or irregular; the shape of the ulcer depends upon the nature of the primary injury received. The edges are undermined, and the margins are raised, indurated and hard to the touch. Sometimes the ulcer gives a 'mouse-eaten' appearance. The ulcer is always covered with a thick grayish-yellow foul-smelling slough with a sero-sanguineous discharge. Sometimes it bleeds on slight touch or on gentle walking. I noticed in a girl an ulcer commencing to bleed whilst she was standing still. It may be very painful at the start, but later on little pain is felt. Lymphangitis is not always present. In some of my cases the affected part presented the appearance of elephantiasis; in one the ulcer completely healed up, but on account of the interference with the venous and lymphatic return his leg was still swollen and oedematous and the condition might have been mistaken for elephantiasis; this may have been due to involvement of the superficial lymphatics in the scar tissue or to obliterative changes in the vessels following septic absorption from the ulcers. The surrounding skin of the ulcer is normally healthy, and little or no constitutional disturbance is present. In some of the cases there was fever for a few days, but this may have been of malarial origin; otherwise the disease is afebrile throughout its whole course.

The ulcer appears to be self-limiting and will eventually heal even when left untreated. One patient refused to have any treatment from the dispensary; I observed him closely and found that he was little the worse for not receiving our treatment; he cured the ulcer in four weeks by applying some 'home medicine'. One cannot be certain whether it was Nature's cure or whether the particular drug healed up the ulcer.

There were no complications in my cases.

Is the ulcer contagious?

Roy (1928) considers that the disease is not contagious. In my series, four of the patients lived in one house, and another two were mother and daughter. On this evidence alone one cannot say whether or not the disease has a tendency to occur amongst members of the same family, but the observation is suggestive.

The problem of immunity.—One attack of Naga sore does not produce any immunity in the victim. One patient had a second ulcer only a few days after his first ulcer was healed up, and another had a second ulcer before his first one was completely cured. However, during this year, about 20 per cent of the newly-recruited coolies were affected, and only about 2 per cent of the old coolies, that is to say, of the 69 cases, 50 were in the former class and 19 in the latter.

Most of the workers in tea districts favour the idea that contamination with soil plays an important part in the causation of the Naga sore. Now the point is, whether long residence

(Continued from previous page)

The use of symptomatic treatment, based on blood findings, is advocated in cases of relapsing malaria.

Symptomatic treatment must be combined with adequate rest, avoidance of fatigue, and the use of suitable hæmatinics.

in a place does confer some sort of immunity upon the people against a particular soil, surcharged with the causative organisms of Naga sore. Another thing to note is that many of the temporary coolies who generally come for work during the rains and go away after some days suffer from similar ulcers. I have omitted them from the report as it was not possible to keep them under observation for any length of time; they generally shift from garden to garden.

Economic loss.—On an average each coolie was disabled from any outdoor work for about 38.14 days. The newly-recruited coolies suffered on an average about 41.04 days, and old coolies about 30.52 days, so the duration of disease was greater in the former than in the latter.

The busiest portion of the year in tea gardens is from June to August and during this period there is shortage of labour in many gardens. Hence the loss of 66 working coolies for a period of 38.14 days is a serious problem, and research on these lines is urgently needed.

Treatment.—Every medical man with a little tea-garden experience knows quite well how difficult and tedious it is to treat these ulcer cases.

Most of the antiseptics in the British Pharmacopœia have been tried without much benefit. 'E.C.' has been much advocated by some Assam workers; in my opinion it is a good drug for subsidiary treatment, but at the start it is not of much use. I have found the following lines of treatment successful:—

(1) As soon as the patient comes under observation with a fully-developed Naga sore, cauterize it thoroughly with pure carbolic acid, until the sloughs separate and the underlying raw surface comes into view. One application may not suffice; sometimes two or three applications will be necessary. Carbolic acid is the only drug that can be relied upon to remove the sloughs. If during the course of treatment sloughs again appear, the ulcer should be again cauterized. It may be thought that these repeated applications will cause poisoning, but I have treated hundreds of cases of Naga sore in this way and have never met with any accident.

(2) After the sloughs have separated, dress the ulcer with any antiseptic dressings you prefer. It may be mentioned here that unless and until the sloughs have separated it is of no use to apply any lotion or antiseptics.

(3) I have tried the following dressings as subsidiary treatment to cauterization with carbolic acid, but I am not in a position to say which is the best because the duration of treatment was almost the same in each case, and unless the patients are detained in hospital and kept under close observation it is not possible to study the merits and demerits of a particular line of treatment:

(a) Washing and dressing with 'E.C.' lotion.

(b) Washing with potassium permanganate lotion, and dressing with plain sterilized gauze.

(c) After washing with these lotions, dusting boro-iodoform over the ulcer and dressing.

(d) Washing and dressing with normal saline.

(e) Dressing with potassium permanganate ointment (1 to 2 per cent).

(f) Dressing with carbolized oil.

(4) As soon as granulation has formed the ulcer should be dressed with some ointment (boric or zinc) or iodox; the latter is better, but it is too expensive for general use.

(5) Iron and arsenic tonic to improve the general condition of the patient.

Throughout the whole course of treatment all patients should be strictly forbidden to do any outdoor work, because it has often been found that contamination of the ulcer with soil when it is almost healed up, results in the recrudescence of the condition, but they may be given light work inside the factory house without any harm.

Some preventive measures

(1) Early treatment of minor injuries such as scratches, thorn-pricks, leech-bites, etc., received during outdoor work. Theoretically, this is a good procedure, but it is very difficult to bring into practice. Coolies will never come up to the dispensary to have their minor injuries dressed. They are sometimes found working in the garden with fully-developed Naga sores on their legs, but if adequate sick allowances are given to those suffering from such ulcers and provision is also made for the families of the sufferers they may be tempted to come to the dispensary or hospital. Companies may have to incur a heavy initial expenditure, but ultimately they will be no losers as they will have increased work during the rains, for duration of treatment will be much shorter if the cases are detected early.

(2) The wearing of putties; this has met with opposition from the coolies specially from female coolies.

(3) Compulsory washing of the legs in some antiseptic lotion (phenyl or potassium permanganate) when they come back from garden work. Two tanks (pucca) one foot deep should be constructed on both sides of the weighing house where all coolies have to assemble twice daily for having their leaves weighed; in these tanks phenyl lotion should be prepared once daily in the morning. Water taps should be fitted in these tanks with outlets, and the tanks so arranged that each coolie will have to walk through this lotion in order to reach the weighing house. In this way all coolies will be compelled to wash their legs four times a day while crossing these lotion tanks. Separate arrangements should be made for entrance into and exit from the weighing house. The size of the tanks

THE INCIDENCE OF CLONORCHIIS INFECTION IN INDIA*

By K. N. BAGCHI, M.B., B.Sc. (Cal.), D.T.M. (Cal. and Liv.), F.I.C. (Lond.)

Public Health Laboratories, Patna

THE literature on the incidence of flukes in India is both meagre and conflicting. The only systematic investigation that has been made in connection with helminthic infections is by Chandler (1928) who states in his detailed

* Read at the Indian Science Congress, Bombay, 1934.

(Continued from previous page)

will depend upon the number of coolies working in the garden concerned.

In addition potassium permanganate may be distributed in small packets to all the working coolies for washing their legs at their homes when they come back from work. This compulsory washing of the legs daily will help to treat early any minor injuries received in the garden.

I take this opportunity of expressing my sense of gratitude to Mr. R. P. Moznunder, the present manager of Ambari Tea Estate, for kindly giving me every facility for treating these cases.

EDITOR, I. M. G.]

survey of the subject that there are no endemic cases of clonorchis or opisthorchis infection anywhere in India or Burma, although they are very common in China and Indo-China. Manson-Bahr, on the other hand, while dealing with the subject of clonorchiasis in his book, refers to Leger who is said to have found 'the eggs in 50 per cent of the natives of the East Coast of India', but Chandler did not find even a single case of clonorchis infection in any of the provinces, although his investigation covered practically the whole of India including the east coast. Only a few sporadic cases of fluke infections other than clonorchis were found in practically every province except Burma. *Fasciolopsis buski* is the one which was commonly met with and it was found almost in endemic form in some parts of Assam. McConnell (Castellani and Chalmers, 1919) reported two cases of opisthorchis infection among Indians in Calcutta and one of clonorchis in a Chinese who apparently got the infection in China, and hence this was not an indigenous infection. Knowles (1923) reported a case of clonorchis infection in Assam, but Chandler believes that it was really a case of opisthorchis which is a very common parasite in cats and dogs in Calcutta and also in other parts of India, especially in eastern India. Besides, the clinical history of the case, as given by Knowles, is against the possibility of any such infection. Byam and Archibald mention that Acton found two cases of clonorchiasis in Mesopotamia among Indian soldiers. On referring to the paper it is seen that Acton (1919) found ova of *Clonorchis endemicus* in two and ova of *Heterophyes heterophyes* in one out of about 3,000 Indian soldiers. As there is no reference in the paper to the condition of the patients in whose faeces the ova were found, it may be assumed that the clinical features of these cases were not in any way suggestive of clonorchiasis, otherwise they would have attracted the attention of a keen observer like Acton and found place in his paper. The eggs found in the stools were probably opisthorchis eggs.

As clonorchis is very common in China, Japan and other Far Eastern countries, there is a likelihood of cases occurring in Burma but Chandler failed to detect any. Manson in describing the geographical distribution of the liver flukes has mentioned India as one of the countries where it is found, but no genuine indigenous case, confirmed either by finding the flukes or by clinical features, has so far been reported.

In Bihar, only two cases of *Fasciolopsis buski* infection were found by Chandler in the districts of Singhbhum and Ranchi and by other observers in Monghyr and Patna. The case I am reporting here appears to be one of *Clonorchis sinensis* infection and was found in Patna. The patient, a Muhammadan male, aged 23 years, consulted his doctor for treatment of anaemia, enlarged spleen and liver and occasional attacks

of fever of irregular and intermittent type—sometimes with only a slight rise of temperature in the evenings. There was a history of geophagy (earth-eating) when he was a boy of fourteen. He was of stunted growth, appeared to have undergone no development during the last nine years of his illness, and looked like a boy of thirteen with all the features of infantilism. There was an irregularity of the bowels—diarrhoea alternating with constipation—and also a history of a mild attack of jaundice a few months ago. He was suspected to have been suffering from kala-azar or malaria with ancylostomiasis as a complication. The examination of his blood and the following blood picture completely negated the possibility of malaria or kala-azar :

Red blood cells	3.37 millions
White blood cells	10,800
Polymorphonuclears	66 per cent
Lymphocytes	18 " "
Large mononuclears	4 " "
Eosinophiles	12 " "
Abnormal corpuscles (microcytes and poikilocytes)	present
Hæmoglobin	45 per cent
Colour index	0.67

No malarial parasites were found and the serum tests for kala-azar were all negative. The urine was normal. The examination of his faeces did not show any ova of hookworms even after the most exacting search by Lane's method for four days. But on the other hand, the first examination of the faeces showed an ovum of brown colour with characteristic operculum and shape. As more were expected, it was not measured and was thrown away and repeated examination of the same stool did not show any more ova. Another sample of faeces was obtained after two days and a thorough search was made for these ova but nothing was found. The third sample on the next day was also negative. The fourth examination after a couple of days more showed three ova in two slides. They were carefully measured and all of them were found to be of about the same size with slight difference in length only. The average dimensions were 27.6 by 15.9 μ , or 28 by 16 μ in round figures.

The colour, shape and size of these ova are quite characteristic of *Clonorchis sinensis*, but it may be noted here that the ova of clonorchis, opisthorchis and heterophyes look very much alike and they cannot always be differentiated under the microscope; the specific diagnosis can only be made satisfactorily by examination of the flukes themselves. In this case no parasites could be detected in any of the samples of faeces, and I was obliged to fall back on the microscopic examination of the ova in all their details and to compare them with typical clonorchis ova, which I had had

with me in a permanent preparation made by me a few months ago in the Liverpool School of Tropical Medicine from an authentic specimen of *Clonorchis sinensis* infection; I found that these specimens resembled each other in minute details. Under these circumstances I did not feel any hesitation in saying that these ova were really the ova of *Clonorchis sinensis*.

The classification of the genus *Clonorchis* into *C. sinensis* and *C. endemicus* is not based on reasonable grounds. They cannot be distinguished and are morphologically identical. The pathogenicity of clonorchis or the intensity of the signs and symptoms depends upon the number of the parasites invading the hosts and not on any morphological features. The question of making any distinction between the two on grounds of pathogenesis is not reasonable, and has not been accepted by Manson.

Apart from the characteristic features of these ova the pathogenicity of this fluke is also a determining factor in establishing its identity. *Opisthorchis* is found as a parasite of cats and dogs in India and other places, but has not been known to produce any disease. *Heterophyes* has so far not been found in India (excepting one found by Aeton in Indian soldiers in Mesopotamia, as already stated), and is not pathogenic. *Clonorchis* is undoubtedly a pathogenic parasite and has not yet been detected in animals in India. The description of the signs and symptoms of clonorchiasis, as given by Manson, corresponds with this case to a remarkable extent, but the patient did not at the time of investigation develop any anasarca, ascites, or intractable diarrhoea, which are generally found in very advanced cases that end fatally. The signs and symptoms of this case indicate an infection of moderate intensity and the treatment given to him so far seemed to have retarded the onset of further complications for the time being. The chronicity of these cases is one of their special features and even the worst cases drag on for several years before they die. In the absence of other causes, the anaemia, the physical signs and the blood picture of the patient could also be explained by ancylostomiasis, but when four examinations of faeces during the course of a week did not show a single hookworm egg, even by the most reliable method of examination, the possibility of hookworm infection can safely be excluded.

Considering the life history of the flukes, the source of infection of these sporadic cases of clonorchiasis in this country is rather mysterious, for the people of India seldom take uncooked fish. It has been proved in China that certain water plants in which the cercariae encyst are also responsible for the spread of flukes in man and Chandler traced the infection of *F. buski* in Eastern Bengal to the eating of 'panifal' or 'singara' (*Trapa bicornis*) which is 'taken raw and commonly peeled by the teeth'. It is therefore quite possible that

'singara' plays also the same part in infecting men with clonorchis.

Summary

The flukes that infect men are very rarely found in India. Chandler reported a few sporadic cases of *F. buski* infection in different provinces, but he did not find a single case of clonorchiasis anywhere in India or Burma, although it is very common in China, Japan, Korea and other Far Eastern countries.

McConnell found clonorchis in a Chinese in Calcutta. Knowles reported the finding of the eggs of clonorchis in the faeces of a man in Assam, and Aeton in two patients among the Indian soldiers in Mesopotamia, but no specific diagnosis was made, either by finding the flukes or by clinical history. The case referred to in this paper is an indigenous one developing signs and symptoms suggestive of clonorchiasis, and typical ova were found in his faeces.

The ova of clonorchis, heterophyes and opisthorchis all look alike and it is very difficult to differentiate them under the microscope.

In China, Japan and other eastern countries the practice of taking uncooked fish spreads infection in man. Certain water plants in China have also been found to harbour encysted cercariae. Chandler traced infection of *F. buski* to eating the common waternuts or 'singara' (*Trapa bicornis*) in Eastern Bengal. It is probable that this waternut which is found all over India may be the source of infection in the sporadic cases of clonorchis and other fluke infections.

[Note.—The evidence that this is a case of clonorchis infection is not at all conclusive as it appears to have been based on the study of three eggs. Up to the present no case of endemic infection with this fluke has been definitely proved in India. The suggestion that sporadic infections of clonorchis may be transmitted, like *Fasciolopsis buski*, by cercariae encysted on the corm of *Trapa bicornis* is not in accord with the known life history of this parasite, as a second intermediate host (a fish), in which the cercariae encyst, is needed.—

FURTHER OBSERVATIONS ON THE METABOLISM OF CAROTENE

By BASHIR AHMAD, Ph.D.

KHEM SINGH GREWAL, Ph.D., M.B., B.S.

and

KHAZAN SINGH MALIK, M.Sc.

(The University Chemical Laboratories, and the Department of Pharmacology, King Edward Medical College, Lahore)

It is now well established that carotene is a precursor of vitamin A, and its transformation into the vitamin is a function of the animal organism. During studies of the mechanism of this change, attention has been focused mainly on the liver, the storehouse of vitamin A in the animal body, and at least one investigator has claimed that the change takes place in the liver through the action of a hepatic enzyme (Oleott and McCann, 1931). But this claim has not been generally substantiated. On the other hand attempts to convert carotene into vitamin A with the help of liver tissue or liver extracts under different conditions have failed, and even the direct perfusion of the intact liver with suitable carotene solutions has not met with any degree of success (Ahmad, 1931; Rea and Drummond, 1932). The more recent observations, however, show that the change of carotene into vitamin A in the animal body may be a slow process, for the formation of vitamin A is not detected until 8 days after the introduction of carotene (Drummond and MacWalter, 1933).

In this study attempts have been made to follow the fate of carotene after its introduction into the venous circulation of an animal. Four different species of animals were used. They were kept on a vitamin-A-free diet for a preliminary period of varying duration depending upon the species of the animal. In rats the depletion of vitamin A can be judged from the fall in weight and the development of the typical eye condition. This is not possible in other animals. Therefore, in the case of animals other than rats, a piece of the liver was aseptically removed by a surgical operation to serve as control for the vitamin-A reserves still left in the body. A few days were allowed to the animal to recover from the effects of the operation. Then a colloidal solution of carotene in 2 per cent glucose was administered for a certain period as a course of intravenous or intraperitoneal injections. After the completion of the carotene administration the animal was killed and its liver and other tissues were examined both for carotene and vitamin A.

The results are summarized in tables I and II.

The rat which can readily assimilate carotene, and conserve large stores of vitamin A in the liver, derived from the pigment fed orally in an oil medium, failed to do so under the condition of these experiments. The administration of a relatively large amount of the pigment did not

TABLE I
(Summary of the result of rat experiments)

No.	Mode and amount of carotene administered	Name of tissue	Weight of tissue, g.	Weight of fat, g.	Total yellow units	Total blue units	REMARKS
2	0.25 c.cm. of colloidal solution containing 0.05 mg. carotene injected into a tail vein daily; 6 injections in 6 days.	liver	0	Both eyes affected; no improvement on the administration of carotene; later, one eye lost; immediate response on oral administration of carotene in olive oil.
4	Total: 0.3 mg. carotene. Do.	liver	0	On the injection of carotene condition became steadily bad, though weight remained almost constant; evidence of a toxic effect; died on the 7th day.
5	0.25 c.cm. colloidal solution daily, containing 0.05 mg. carotene into one of the tail veins; 9 injections in nine days.	liver	0	On the administration of carotene condition became bad; developed diarrhoea; died on the 21st day after the first injection.
	Total: 0.45 mg. carotene.						
15	0.25 c.cm. colloidal solution containing 0.05 mg. carotene into one of the tail veins on alternate days. 10 injections in 20 days.	liver	7.15	0.130	7.0	0	The carotene injections did not affect the general state of health; weight remained steady, eyes unaffected; killed five days after the last injection, and no vitamin A in the liver.
	Total: 0.5 mg. carotene. Do.	kidneys	0.295	0.038	0.5	0	
		tail	..	0.05	4.5	0	
16		liver	4.47	0.141	6.0	0	Do.
		kidneys	0.52	0.04	0.5	0	
		tail	..	0.55	7.5	0	
		liver	0	
11	9 injections of 0.25 c.cm. solution daily containing 0.05 mg. carotene each for 9 days, intraperitoneally.						Weight rose slightly on the administration of carotene; general condition remained unchanged; killed five days after the last injection. No vitamin A detected in the liver post-mortem.
	Total: 0.45 mg. carotene.						
17	Ten injections of 0.25 c.cm. solution containing 0.05 mg. carotene each, on alternate days in a period of 20 days, intraperitoneally.	liver	5.54	0.114	6.5	0	On carotene injection weight slightly rose; general condition unaffected; killed five days after the last injection. No vitamin A detected in the liver. (Kidneys were enlarged and appeared to be congested).
	Total: 0.5 mg.	kidneys	0.62	0.042	0.9	0	
		spleen	0.56

		kidneys	0.42	0.35	0.7	0	
			0.41				
		spleen	0.21	0.042	1.0	0	
		intestines	..	0.041	trace	0	
		omentum	..	0.034	3.7	0	

Intravenous injections were given in one of the veins of the tail. In two animals (nos. 15 and 16) post-mortem examination of the tails was made. Subcutaneous yellow deposits of carotene were noticed at some places. These were presumably spots where the carotene solution had been injected during trials before the needle actually got into the vein. The ether extract of the tail was yellow but the fatty residue showed no blue colour on the addition of antimony trichloride reagent.

Animals nos. 17 and 18 also showed one or two patches of the subcutaneous deposit of carotene formed similarly as in the tails of rats nos. 15 and 16. No such deposit of carotene could be detected in the peritoneum. Omentum was distinctly yellow but showed no blue colour reaction.

Colloidal solutions of carotene were prepared fresh each time for the injection.

result in the formation of any detectable quantity of the vitamin, and even failed to relieve the eye condition or loss in weight arising from

the deficiency of vitamin A. Indeed in some cases the injections of carotene appeared to have a toxic effect upon the animals, though such

	Do.							Initial period of vitamin-A-free diet consisting of dried wheat and barley, 32 weeks (7½ months). Died next day after the operation; death due to ileus and not hæmorrhage from the liver. Post-mortem appearance of the various tissues was normal. The sections showed no keratinization of the epithelium anywhere.
Rabbit 9	5 c.cm. solution containing 0.5 mg. carotene was injected into the ear vein. Ten injections were given during a period of 21 days, one each alternate day. Total: 5.0 mg. carotene.	liver before injection.	16.81	1.04	trace	0	0	The animal was on a vitamin-A-free diet consisting of dried wheat and barley for an initial period of 19 weeks. Weight was nearly steady during the last few weeks and appeared to be depleted of the body stores of vitamin A which is confirmed by the examination of the control liver. There is an evidence of the formation of vitamin A in the liver from the administered carotene.
		liver after injection.	16.81	0.273	100	330	19.5	
		kidneys	5.02	0.14	5	0	0	
		spleen	0.265	0.017	10	0	0	
		small intestine.	10.5	0.023	0	0	0	
		large intestine.	23.7	0.016	0	0	0	

effects were not noticed on other animals in a relatively better state of health. Further, no evidence of the change of carotene into vitamin A could be obtained when similar injections were given into the femoral vein of a dog. Only in the case of the rabbit did it appear that vitamin A found in the liver was derived from the administered carotene.

The question arises as to how this large quantity of the pigment so introduced into the circulation is disposed of by the organism. It cannot be detected in the blood, nor is it excreted in the urine, unless it is completely changed into

products with different physical and chemical properties. The liver and the spleen are the organs which show an increase in their yellow unit content after carotene administration.

It was previously suggested that on account of their other similar activities the reticulo-endothelial cells may be concerned in this process (Ahmad and Malik, 1933). It now appears that such a view is not improbable. The reticulo-endothelial cells, on account of their capacity of phagocytosis and intracellular digestion, probably constitute the normal mechanism of the body for dealing with any foreign colloidal

matter, animate or inanimate, that gains access into the circulation. After the injection of carotene the pigment appears to be chiefly localized in the liver and the spleen (table II)—organs which are the chief storehouse of the reticulo-endothelial cells. More indirect evidence also seems to indicate similar conclusions. The evidence of the formation of vitamin A after the injections of colloidal carotene into the circulation has only been obtained in the rabbit, while it failed in other species of animals under similar conditions. Of all the experimental animals the reticulo-endothelial system of the rabbit is regarded to be functionally more powerful, as it responds more quickly in immunization experiments. The rôle of certain cells (histiocytes) of the reticulo-endothelial system in the phagocytosis and ingestion of red-blood cells and the formation of bilirubin is familiar and not unanalogous (McNee, 1923). Several investigators have indicated a possible relationship between the reticulo-endothelial cells (monocytes) and antibody formation which furnishes further analogy (Pfeiffer and Marx, 1898; Hektoen and Carlson, 1910; Leukhardt and Becht, 1911; Topley, 1930; Napier, Krishnan and Lal, 1933). Finally it may be pointed out that, with the exception of the spleen, there is some parallelism in the concentration of vitamin A and the reticulo-endothelial cells in the animal body, though possibly the formation and storage of vitamin A may be a function of the different types of reticulo-endothelial cells.

All this evidence is perhaps not more than suggestive. The confirmation of this view could only be made after the method and technique of demonstrating the presence of both carotene and vitamin A within the individual cells is developed.

In the end we wish to thank Professor S. S. Bhatnagar and Lieutenant-Colonel D. H. Rai for allowing us the facilities of their laboratories for this work. Our thanks are also due to Pandit Vishwa Nath for the post-mortem examination of the goat.

PREVENTION OF CHOLERA IN RURAL INDIA

By SARANJAM KHAN, B.Sc., M.B.B.S., D.P.H.
D.T.M. & H.

Additional Assistant Director of Public Health
North-Western Frontier Province

It is a well-known fact that drinking water plays an important rôle in the spread of cholera. By the introduction of the municipal water supplies, cholera has ceased to be of such serious importance in the towns of India as it used to be previously. At the present time cholera is a problem of the villages.

Our present methods of dealing with cholera are of the *suppressive* rather than *preventive* type. Any organization for the control of the disease is put into action after an epidemic of cholera has already started; this can never be successful.

On the other hand if we can ensure the safety of drinking water in the villages, this will be a real preventive measure which will go a long way towards eradicating the disease.

In the majority of the cholera provinces of India the chief sources of water supply are ground wells, and they are also the chief sources of the epidemics of cholera. It is impossible to do away with these wells and the tube-well has been a failure. The safeguarding of these wells will be a real preventive measure against cholera. Besides, pure drinking water is a rare commodity in the villages. The constant use of polluted water may or may not injure the vitality of the villagers in the long run, but it is imperative to protect such water from becoming a veritable source of disease and death.

The device described below is meant to protect the village well from contamination; these details are published in the hope that its adoption may lead to the prevention of the spread of this disease.

Any device for protection of the village well must fulfil the following essential requirements:—

- (a) It must be cheap, that is, within the resources of the villagers;
- (b) it must be simple; every village carpenter should be able to make it or repair it from material available in the village; and
- (c) it must be effective in protecting the well from pollution; if bathing or washing is done near it, polluted material in bulk or in the form of droplets should have no chance in getting into the well.

(Continued from previous column)

- Rea, J. L., and Drummond, J. C. (1932). *Zeitschr. Vitaminforsch.*, Vol. I, p. 177.
 Topley, W. W. C. (1930). *Journ. Path. and Bact.*, Vol. XXXIII, p. 339.

Nobody should be able to lower his own bucket, but everybody should be able to draw water when required. The well must be completely covered at the top in such a way as to be easily uncovered at any time whenever it is necessary to clean the well or repair the apparatus, and the covering easily placed again

2. *Collecting board with tap.*—It should be in the shape of a boat and may be made by joining several wooden boards of convenient size. The water from the bucket is discharged on to this board from where it runs out through a tap. The size and shape of the board are designed to serve the purposes of (a) collecting

Fig. 1.

when the cleaning is finished. The well must be capable of being used in the ordinary way whenever so desired.

Below is given a description of a contrivance that fulfils these requirements and the manner in which it should be constructed. The following materials are required (see figure 1):—

1. *Iron bucket.*—The size should be convenient. It must be oval in shape and the bottom pointed, such as is usually used in villages. The pointed bottom ensures its falling on its side and discharging its contents of water.

water towards the tap; and (b) allowing the bucket to fall freely on its side.

3. *A rope of sufficient length for carrying the bucket.*

4. *The drawing pulley.*—This is supported on two wooden poles. It is turned by hand. The rope winds round it. It is used for pulling up and lowering the bucket.

5. *The push bar.*—This is a bar (made of wood or iron) with a loop at one end through which the rope passes. By means of this bar the bucket is pulled on to the collecting board

for discharging the water and pushed off the board again for lowering into the well.

6. *The cross-bar pulley.*—A narrow pulley working on a cross bar over which the rope passes. By this pulley the bucket is kept clear of the collecting board.

7. *The covering boards.*—They completely cover the well and a chain and hook are provided for locking them. The boards should be removable when required.

A masonry wall of backed bricks about five feet in height and one foot in thickness is built around the mouth of the well which is on the ground level. (The height and thickness may be varied considerably according to the requirements). The diameter enclosed by the wall is the same as that of the well (see figure 1).

8. *The delivery tap.*—This may be made of iron; it projects from the outer surface of the wall for a few inches and is about one and a half feet from the ground level. This tap goes through the thickness of the wall and delivers water from the collecting board which is on the inner side of the wall. The lumen of the tap is about one inch in diameter.

9. *The collecting board.*—This projects into the lumen of the well at the level of the delivery tap. It must slope slightly towards the delivery tap from all sides. The size of the board is according to the circumference of the well. One side is firmly fixed into the wall and the other side which projects into the lumen of the well is fixed firmly to a cross bar. This is to give strength, and the whole board should be strong enough to stand the constant play of the bucket on it. The board must not leak. It may be made by joining several boards as is done in making a boat.

The push bar passes through a hole in the wall on the same side as the delivery tap at a suitable height to be easily worked by the right hand while the left hand is on the drawing pulley. Also it must be sufficiently above the collecting board to keep the bucket free from the collecting board. One end of the push bar has a loop or hole at the end, through which the rope passes freely. The push bar must play freely in the hole in the wall. The ends of the hole in the wall may be strengthened by building wooden blocks (B) into the masonry. It must be of sufficient length to keep the bucket clear of the collecting board and must not produce any kinking of the rope. The outer end of the bar must be shaped in the form of a handle (C) of sufficient thickness to prevent it falling into the well.

As the bucket is pulled up and has reached above the level of the collecting board, the handle of the bucket engages in the loop of the push bar (see figure 2). At this moment the push bar is pulled by the handle for a convenient distance, and at the same time a slight movement of the drawing pulley in the reverse direction, as in lowering the bucket,

allows the bucket to be drawn on to the upper surface of the collecting board (see figure 3). The bucket is released there by a further movement of the drawing pulley. As the bottom of the bucket is pointed, it falls on its side, and if the collecting board is so made as to allow this to occur without impediment, the bucket is almost completely emptied, and the water runs out of the delivery tap. After the bucket is emptied, it is lifted up by a slight turn of the

Fig. 2.

drawing pulley in the right direction (*viz.*, in the direction of drawing up the bucket) and pushed out by the push bar clear of the collecting board. It may then be lowered into the well again.

The cross bar pulley (see figure 4) plays on a cross bar of sufficient length and thickness. The cross bar is placed on the top of the wall. It is placed across the wall at such a distance as to keep the rope and the bucket clear of the collecting board. On the central part of the

Fig. 3.

Fig. 4.
Drawing pulley.

A METHOD OF PLATING STOOLS

By D. READ

CAPTAIN, I.M.S.

District Laboratory, Kohat

THE following method of plating from stools has given satisfactory results in the district laboratory, Kohat. Some idea of the value of the method may be gathered from a perusal of the first hundred cases so dealt with. It is not however claimed that these results should be accepted as typical.

Method.—A saline suspension of the stool is prepared by the sweeper, centrifugalized to remove large particles and standardized to no. 3 or no. 4 Brown's opacity tube. From this one drop from a pipette standardized to no. 30 BSWG, which gave a volume of approximately 0.03 c.cm. with normal saline, is dropped into 20 c.cm. of normal saline and mixed. Care should be taken to draw up only one drop into the end of the pipette, and the same pipette can then be used for mixing the dilute solution so formed. After mixing, 10 drops with the same pipette are placed equally spaced over a 3½ inches bile-salt-litmus-lactose-agar plate and spread by rocking or rotating the plate between the fingers. By this method in many cases a perfectly even spread of between 50 and 200 colonies can be obtained.

Taking into consideration the effect of acid spread from acid-forming colonies, approximately 100 colonies was found to be the most convenient with a plate prepared to a pH. of 7.5. It will be clear that, as no part of the plate is more thickly spread than another, the chance of isolation of pathogenic organisms is greatly increased. Unfortunately, owing to the impossibility of gauging the proportion of viable and non-viable organisms in the emulsion, plates were sometimes too thinly, and rarely too thickly, spread.

The results obtained in a hundred trials are summarized below :—

- (a) Approximately 100 colonies on 37 plates.
- (b) Well over 100 but less than 200 colonies on 9 plates.

(Continued from previous column)

cross bar is located the cross bar pulley. The rope of the bucket passes over this pulley and then through a notch in the top of the wall and is attached to the drawing pulley. Both the pulleys are in the same level so that the rope is kept in a straight line horizontally from the cross-bar pulley to the drawing pulley (figure 1). The notch in the wall over which the rope passes allows sufficient room for the free play of the rope without any friction.

The rope is wound round the drawing pulley, which is turned by means of the projecting bar (figure 4). The play of the drawing pulley is restricted to the central part of the wall by the nails 'N'.

(c) Well under 100 but more than 50 colonies on 21 plates.

(d) More than 200 colonies on 20 plates.

(e) Less than 50 colonies on 13 plates.

These 100 plates were prepared from stools of individuals presenting themselves for carrier examination; none of these stools contained any mucus. The following organisms were isolated :—

Bact. flexneri—on three occasions,

Bact. typhosum—once, and

Non-mannite fermenters, indol positive—twice.

These six plates from which the above organisms were isolated all belonged to groups (a) or (b) of the above classification. Two strains of *Bact. flexneri* were isolated from (b), that is, plates on which there were more than 100 colonies but less than 200, and the rest from (a), that is, plates with approximately 100 colonies.

Control.—In a parallel series plated by the loop method no organisms were isolated.

The following are the advantages of this method :—

(1) It is standardized.

(2) If the technique is followed with even a moderate degree of accuracy, the results are good. Plating by ordinary methods requires experience.

(3) The whole plate is usefully employed.

The following are the disadvantages :—

(1) A sterile plate, or an almost sterile plate, may be obtained with annoying frequency, though this will also occur by the loop method.

(2) It takes time.

(3) It cannot of course be used for mucus-containing stools.

[*Note.*—An additional disadvantage in this method is that it demands an absolutely sterile plate, an ideal it is difficult to achieve with certainty in the hot humid plains of India. A small overlooked colony would lead to contamination of the whole plate, whereas by the loop method quite a large colony can be avoided.—*EDITOR, I. M. G.J.*

A NEW CAPSULE FORCEPS

By G. JOSEPH GNANADICKAM

Swedish Mission Hospital, Tirupatur, Ramnad District, South India

WITH reference to my paper in the *Indian Medical Gazette* of October 1932, on the intracapsular extraction of the senile cataract, I have been receiving many enquiries as to the forceps I recommend.

I was then using both Stanculeanu's and Elschmig's forceps; each had its own merits. Messrs. John Weiss and Son of London have made for me a new forceps, combining the advantages of those two forceps in one, and

eliminating their respective disadvantages to some extent.

This instrument is about the size of Stanculeanu's forceps, but the blades are very like Elschmig's. The double curvature on the blades is so shaped as to give a proper grasp of the capsule in its lower portion without touching the centre or pushing the cornea too much forward. The grip is firm, but never tearing.

The blades themselves are thin, taking very little space in the anterior chamber. The size of the handles and the spring action are such that one could actually feel the force used in the pinch.

I have so far used the forceps on over 500 cases and have found it to be very satisfactory. The above illustration shows the actual size of the instrument.

NUTRITIVE VALUE OF MUSTARD OIL

By B. B. BRAHMACHARI, D.P.H.

Director of Public Health Laboratory, Bengal

As I have shown in my article on the vitamin value of the food fats of Bengal (Brahmachari, 1932), mustard oil, i.e., the oil expressed from the seeds of the mustard plants, and ghee are the only two fats which enter, as such, into the dietary of the people of Bengal, and, of the two, mustard oil is the more important. It is taken throughout the province, in towns as well as in villages, with their daily food by the rich as well as the poor, while ghee is used more in towns than in villages, and is more or less limited to the well-to-do and the middle class

Weight increase in two rats on basic diet and mustard oil plus spinach.

people. As a rule mustard oil is cooked with the other food articles; but occasionally it is also taken mixed with boiled potatoes and other

vegetables, boiled eggs, roasted brinjals, etc. Though of such importance as food, it does not seem to have been studied from the point of view of its nutritive value.

In my article referred to above, it was shown that mustard oil does not contain any vitamin A. In studying the vitamin value of the *kacha* ghee, i.e., ghee that has not been hard boiled, we had to test this oil again on three rats as control. The basal diet was the same, viz,

Casein	19 units
Starch	55 "
Yeast	5 "
Salt mixture (McCollum and Simmonds, 1918)	5 "

To this was added, as the fat portion of the diet, 16 units of mustard oil.

The three rats were all of the same litter, all females, born on the 23rd May, 1932. The experiment was started on the 14th July next, i.e., when they were seven weeks old and all weighed 70 grammes. They fared as follows :—

Weight increase in rats of a basic diet to which different oils have been added, as fat.

The nutritive value of mustard oil as compared with that of the other edible oils and fats.—For the experiment, we used the same diet as before, the fat being represented by the

WEIGHT IN GRAMMES ON VARIOUS DATES

Serial number	14/7	21/7	28/7	5/8	12/8	19/8	26/8	3/9	12/9	16/9	20/9
1	70	40	60	50	50	60	50	50	50	50	50
2	70	50	60	50	50	60	60	70	60	60	60
3	70	50	60	50	60	60	70	70	60	60	60

On the 20th September, i.e., after a period of nine weeks, they were below the weight at which they had started and were developing xerophthalmia. As their subsequent fate was obvious, the experiment was discontinued.

respective fats under experiment. The casein, however, was not soxhleted nor heated to destroy the vitamin that might be contained in the trace of milk fat remaining in it. The result is shown in the following table :—

WEIGHT IN GRAMMES ON VARIOUS DATES

	Date of birth	Fat given	WEIGHT IN GRAMMES ON VARIOUS DATES									
			21/10	27/10	3/11	10/11	18/11	25/11	2/12	9/12	16/12	23/12
Male	18-8-32	Ghee	50	60	70	80	100	110	120	140	150	160
Female	"	"	50	60	70	80	90	100	110	110	120	130
Male	"	Arachis oil.	50	65	80	110	125	145	150	165	175	170
Female	"	"	50	65	70	80	90	100	110	120	145	littered
Male	21-8-32	Sesame oil.	50	65	75	90	110	120	120	130	140	150
Female	"	"	50	70	80	85	105	110	110	120	littered	..
Male	"	Linseed oil.	60	70	80	80	105	120	120	125	130	130
Female	"	"	40	50	60	60	70	75	90	littered
Male	"	Coconut oil.	60	70	85	100	120	130	140	160	175	185
Female	"	"	50	60	65	75	90	100	100	115	115	125
Male	"	Mustard oil.	50	50	50	60	60	70	60	80	90	90
Female	"	"	40	died 24/10

Growth of the rats was quite satisfactory with all the fats except mustard oil. Coconut oil is shown by McCarrison (1929) to contain some vitamin A, but to be poor in it, and gingelly (*i.e.*, sesame oil), linseed oil and ground nut (*i.e.*, the arachis oil) to contain very little. So the growth under them is largely due to the trace of milk fat which was in the casein and

vitamins A, B and C. So I next proceeded with six rats of the same litter born on 19th December, 1932, placing them under the same diet containing mustard oil, but adding enough of spinach for vitamin A. The experiment was started on the 13th February, 1933, *i.e.*, when they were 8 weeks old, with the following results:—

WEIGHT IN GRAMMES ON VARIOUS DATES											
		13/2	20/2	27/2	6/3	13/3	20/3	27/3	3/4	10/4	18/4
Male	..	70	70	100	120	125	125	140	150	150	170
Female	..	50	50	60	90	100	110	120	130	littered	..
Male	..	70	70	90	120	130	140	150	160	170	..
Female	..	50	50	60	80	85	100	110	150	littered	..
Male	..	70	90	100	130	140	150	160	170	170	200
Male	..	40	60	70	100	115	120	130	140	150	160

was not removed, nor rendered inert, as in the previous experiments. If so, the poor growth under the mustard oil with the same casein is analogous to the phenomenon observed by Fridericia (1924); he found that by adding hydrogenated whale oil to a diet in which the vitamin was supplied by butter fat the vitamin A of the latter was inactivated. In this case the mustard oil appears to have inactivated the vitamin A in the casein.

The nutritive value of mustard oil when given along with sufficient quantity of vitamin A.—Spinach is known to be rich in vitamins; McCarrison shows it with three crosses (*i.e.*, rich in vitamin) under each of the three

Conclusion.—We may fairly conclude that mustard oil—

- (i) is entirely destitute of vitamin A,
- (ii) tends to inactivate vitamin A in other food articles given along with it,
- (iii) but, as fat, is as nutritive as other fats, provided sufficient vitamin A is supplied in other articles of food.

A Mirror of Hospital Practice

A CASE OF WEIL'S DISEASE OR INFECTIVE JAUNDICE

By A. D. LOGANADAN

MAJOR, I.M.S.

ASSISTANT SURGEON C. M. E. EYLES, I.M.D.

and

SUB-ASSISTANT SURGEON BACHAN SINGH, I.M.D.
 Burma District, Maymyo

A BRITISH OFFICER, aged 52, stationed in Maymyo since February 1933, reported sick on the morning of the 29th September, 1933, complaining of headache and severe pain in the limbs, especially the legs.

Temperature varied between 99° and 101°F., the pulse was irregular and there were frequent extrasystoles. He fainted in the toilet room that evening, and was therefore admitted into the British Military Hospital, Maymyo, the same day.

Previous history.—He had been out snipe shooting three times at intervals of seven days, each time to the same spot, the sixth mile stone from Mandalay, east of the road. The last time was on the 27th September, 1933, *i.e.*, two days before reporting sick. He said that on that day he felt off colour and owing to pain in the legs he could not cover the usual long distances even after long intervals of rest.

Progress in hospital.—The patient ran an irregular temperature, ranging from 99° to 101°F., for four days, the pulse becoming more regular with rest. On the 2nd October, 1933, he was slightly jaundiced and the breath was offensive, and was put on fat- and protein-free fluid diet.

Urine examination: Specific gravity—1016, acid, smoky, albumin present and the deposit showed a few pus cells, red blood cells and epithelial cells.

3rd October.—Jaundice greatly increased; urine—8 ounces; sweated profusely, clothes having to be changed five times.

4th October.—Jaundice increased; bowels not opened; had not passed urine since previous midday; was put on alkaline diuretics and antiphlogistine applied over loins.

5th October.—The temperature was down to normal; he spent a restless night; bowels opened thrice after salts; stools clay-coloured; no urine passed; dry cupping to loins twice a day; catheterized urine—three ounces; blood pressure 110/73.

Laboratory findings:—

White blood cell count 16,000 per cubic millimetres

Differential count—

Polymorphonuclears	93 per cent
Lymphocytes	6
Large mononuclears	1

Blood smears were negative to malarial parasites and spirilla of relapsing fever.

Urine	no deposit
Urea	0.8 per cent
Albumin		++	
Blood urea	0.116 per cent

Van den Bergh's reaction was 'direct immediate'.

Two guinea-pigs were inoculated intraperitoneally, one with two cubic centimetres of blood and the other with centrifugalized deposit of urine.

6th October.—Patient complained of loss of memory; later in the evening was drowsy; clay-coloured stools passed three times after salts; urine not passed; catheterized urine 1½ ounces, showed a thick deposit containing pus cells in large numbers entangled in fibrinous strands, there were only a few leucocytes, no red blood cells or casts; 18 ounces of blood was withdrawn and 40 cubic centimetres of 30 per cent saline was run into the vein; frequent feeds of orange juice containing glucose were given.

7th October.—Urine not passed; catheterized specimen measured 92 cubic centimetres; albumin 0.01 per cent. Urea 0.7 per cent. Deposit showed pus and renal cells, epithelial and granular casts; no red blood cells, no leptospira seen under dark-ground illumination.

Blood urea—0.126 per cent. Culture—*B. coli* isolated. Patient slept for long intervals with the help of chloral hydrate; did not perspire but skin was moist and warm; was beginning to show signs of air hunger in the early afternoon; was restless and delirious and was with difficulty restrained from getting out of bed; respiratory distress much relieved by oxygen; had a mild uræmic convulsion at 5 p.m. Patient died at 7-10 p.m.

Report on the animal inoculation

The guinea-pig inoculated with centrifugalized deposit of urine on 5th October, 1933, was still alive and well on the 28th October.*

That inoculated with 2 cubic centimetres of blood looked healthy and normal till the evening of the 16th October, when it had its usual food, but on the morning of the 17th October, it was seen to be intensely jaundiced, was very ill, lying still with increased respiration. Died at 10 a.m. and a post-mortem examination was immediately carried out.

Post-mortem examination.—Serous membranes and muscles were intensely jaundiced. Subcutaneous fat and fat about the kidneys was deep yellow; extensive subcutaneous hæmorrhages were seen all over. Lungs shrunken with extensive hæmorrhagic patches. The liver was normal in size, but yellow in colour. The kidneys were swollen and tense and on section the substance bulged on account of tension. The supra-renals appeared normal.

Blood from heart, and urine from bladder, showed no leptospira, under dark-ground illumination or Giemsa's and Fontana's stain. Culturally no growth was obtained in serum medium (Fletcher's) for 8 days at room temperature.

* [Leptospiræ do not appear in the urine before the end of the second week, usually when the patient is convalescent. In this case it was the 7th day of definite illness—the 9th day if the two days of malaria are included—when the guinea-pig was inoculated with urinary deposit; it is not surprising therefore that it survived. On the other hand, an interesting feature of the case is the infection of the other guinea-pig; the leptospiræ usually disappear from the blood before the end of the first week of the disease.—EDITOR, I. M. G.]

Sections of liver stained by Levaditi's method show a great number of leptospiræ in between the cells.

Sections of kidneys by Levaditi's method also show leptospiræ, but they are fewer, scattered here and there.

Sections stained by Giemsa's, Leishman's and hæmatoxylin Biebrich scarlet did not reveal any leptospiræ.

Comments.—The interesting points in this case are:—

1. At the time the patient reported sick, there was a mild but extensive epidemic of influenza amongst the Burman troops, so a provisional diagnosis of influenza was made. Fainting in quarters and the irregular heart necessitated early admission into hospital.

2. The patient showed signs of defective functioning of the kidneys very early in the disease. As he was heavily built and rather plethoric a large white kidney was suspected.

3. The early intense jaundice with a total white count of 16,000 per cubic millimetres and absolute and relative increase in polymorphonuclears made one suspect Weil's disease group. Though the blood was inoculated on the ninth day of the disease the guinea-pig was successfully infected.

4. Taylor and Goyle in their account of an epidemic of leptospirosis in Andamans (*Indian Medical Research Memoirs*, No. 20 of March 1931) mention a typical case in the Rangoon General Hospital in which they were able to demonstrate leptospira in the kidney.

No other case has so far been reported as having occurred in Burma.

Our thanks are due to Captain C. A. Levy, R.A.M.C., for allowing the use of his notes on the case and also to Lieutenant-Colonel A. H. T. Davis, Commanding British Military Hospital, Maymyo, for permitting publication of this case.

A CASE OF PROLAPSED UTERUS*

By M. A. GHANI, L.M.F. (Bengal)

Medical Officer, Civil Dispensary, Bag (Gwalior State)

RECENTLY, I was called to see a Hindu female, a multipara, aged about 25 years. She had been delivered of a normal male child eight hours before, with the assistance of a *dai*. The latter had extracted the placenta so forcibly that the uterus was completely extorted. The *dai* and several other persons had tried to replace the uterus without success.

At first, I tried to replace the uterus without an anæsthetic, but the patient could not stand the pain, and her vaginal muscles were also very rigid, so she was given chloroform. The foot of the bed was raised and the patient's legs were held up, when the uterus was easily replaced. A firm bandage was applied and she was given a quinine and ergot compound three times a day, and she made an uneventful recovery.

It is remarkable that there were no signs of sepsis although the uterus had been extensively handled by the *daïs* without any antiseptic precautions.

Indian Medical Gazette

JUNE

TROPICAL PHAGEDÆNIC ULCER (NAGA SORE)

Of the non-fatal diseases that occur in tropical countries one of the most important is tropical phagedænic ulcer, or *ulcus tropicum*. From the personal point of view the disease is important because it is painful, disabling, and difficult to treat; the most likely victim is the bread-winner of the family, and he is incapacitated at a time of year when his services in the fields are most valuable. From the point of view of the employer of labour it is important because the ulcers are liable to appear in epidemic-like waves and he may suddenly find a large percentage of his carefully-nursed force unable to work at the busiest season of the year, and because there do not seem to be any short cuts to treatment nor any well-defined preventive measures to be adopted.

The individual sufferer usually finds that he gains little official sympathy until he can contrive to swell the mortality returns, and, as *ulcus tropicum* is not a recognized cause of death, he, as an individual, would normally have been left to suffer in silence and to apply cowdung or whatever domestic remedies are in vogue in the particular part of the country where he is living; when, however, the individual becomes a unit of a labour force, his enforced idleness is a matter of concern to others besides himself, the disease from which he is suffering acquires a greater degree of importance, and action is demanded from the medical profession. It is possibly for this reason that *ulcus tropicum* has acquired a reputation as mainly a disease of tea-estate labour forces; it is known that the disease does occur amongst the field workers of the rural population in different parts of India, but from the available returns it is difficult to estimate to what extent its special affinity for tea-estate labour forces is real and not merely apparent.

Elsewhere in this issue will be found a paper on Naga sore, contributed by a tea-estate medical officer. The name 'Naga sore' is one of the many local pseudonyms that *ulcus tropicum* has acquired, and it is probably the one in most common use on tea estates in India. In his covering letter the writer apologizes for not having carried out any bacteriological investigations and for his failure to record any new facts. His apology is unnecessary; tea-estate medical officers seldom have the time or the facilities for carrying out bacteriological investigations, but they are in a position to report epidemiological and clinical observations which may be of great value to the investigator

who is trying to unravel the problem of the prevention and treatment of this condition, and are infinitely more useful than the spasmodic and pseudo-scientific essays at the problem with the help of the microscope that are usually claimed as 'research'.

There seems to be no longer any doubt that the pathology of Naga sore is similar to that of *ulcus tropicum*. In 1921 Fox (*I. J. M. R.*, VIII, 694) showed that the fusiform bacillus and the spirochæte could usually be recovered from a typical sore, but Roy (*I. M. G.*, LXIII, 673) found that, though the typical fusiform bacillus could be found in most of the cases he investigated, the associated spirochæte was only rarely present. Acton and Panja in 1932 investigated the pathology and bacteriology of Naga sore on some coolies sent down to the School of Tropical Medicine from the tea districts; they showed that the fusiform bacillus, an anaerobe that could be isolated and cultivated with comparative ease in a special medium, when inoculated by itself did not give rise to any ulceration, but, when it was inoculated with either the pyogenic cocci or the diphtheroids that were often present in the ulcers, the typical ulcer followed. In their inoculation experiments they were able to produce the typical ulcer on the leg; but inoculations on other parts of the body resulted only in abortive lesions. They cut histological sections of these ulcers and found that 'the edges were undermined and on the floor of the ulcers there was a slough; under this slough the fusiform bacilli formed a dense felted layer on a vascular granulation layer, the granulation tissue extending to the fascia', to quote from Colonel Acton's report. The ætiology of the ulcer thus becomes clearer; a septic wound or an infection of the skin is an essential precursor; on to this the fusiform bacillus is superimplanted; this bacillus produces a membrane-like slough under which anaerobic conditions are maintained and the organism flourishes. The observations that the ulcers are more easily formed on the legs is important. Other observers have also drawn attention to the fact that they tend to form on the parts of the skin where the blood supply is poorest. The spirochæte, *Spirochæta vincenti*, does not appear to be a constant finding and there is no evidence that it plays any part in the pathology of the disease.

Nothing definite is yet known about the method of spread of the infection and recent work has not thrown any new light on the epidemiology of the disease. It is very definitely seasonal; practically all published records show June as the month of highest incidence, that is to say, it is associated with the onset of the rains rather than with their full development. It occurs mainly in coolies working amongst the tea bushes rather than amongst those working in the factory, and Roy claimed that in a village where half the inhabitants

were part-time employes on a tea estate and the other half were working in their own fields only the former were infected; this is a very important point and worthy of more thorough investigation.

Again, infants and young children appear to escape, whereas adolescents and young adults are most frequently attacked. The incidence amongst men is slightly higher than amongst women. This distribution of the incidence of the disease amongst various groups, age, sex, and occupational, may be explainable on the grounds that the groups most liable to predisposing injuries are most heavily infected, but more figures regarding the relative incidences within the various groups are necessary before this explanation can be accepted. The usual explanation is that the coolies working amongst the tea bushes are very liable to get their legs scratched, but it is interesting that in Roy's series trauma was not the main predisposing cause; for example, in 222 cases of ulcer on the leg, trauma was given as the predisposing cause in only 82, or 37 per cent, whereas 'itching from dermatitis' was the story in 100 cases.

According to Dr. Ghosh's observations, new coolies are more often affected than those who have been established on the garden for a year or more. At the same time there is little evidence that any immunity is acquired by an attack; instances are frequently reported of a fresh ulcer commencing before the first has completely healed up, and the same coolie will often get an ulcer about the same time, year after year.

There is little evidence that the disease is spread directly from one person to another, as a general rule; in fact, experimentally the ulcers are not easily produced. Dr. Ghosh reports four cases from the same family, but the association here may have been in the predisposing factor; and family incidence is not usually reported.

The 'eye-fly', *Siphonella funicola*, is popularly associated with actual transmission of the infection from one person to another. The period of greatest activity of these flies coincides with the period of greatest incidence of the disease, and they certainly settle on the sores and become a great source of annoyance to the patients, but there the case against this fly seems to end. Experimental work with the eye-fly has given no support to this theory; failures to transmit the disease experimentally need not be taken too seriously, but Roy demonstrated that when these flies do ingest the fusiform bacillus it shows signs of rapid degeneration, and there are epidemiological facts that are difficult to explain, e.g., the extreme rarity of lesions on the upper parts of the body—though above we have suggested another possible explanation for this—and the distribution amongst the different age, sex, and occupational groups. It seems far more likely that the fusiform bacillus is a free-living organism associated with

certain types of soil, reaching its maximum development at the end of the hot weather; being an anaerobe it would not be spread in the dust—even if it could withstand the desiccation—but would normally remain below the surface to be disturbed and spread in the first mud of the rains, and later as the rains continue it would be washed out of the soil.

The irregularity of the incidence of the disease—its frequency in one district and rarity in another, and the variations in its incidence from year to year—might easily be explained by fundamental differences in the soil or by differences in the manurial treatment to which the soil has been subjected.

The factor that does not seem to have been taken into consideration with references to Naga sore in India, though it has been with reference to ulcer tropicum in other parts of the world, is the nutritional factor. In Africa, calcium deficiency has been suggested as a predisposing cause, and calcium and parathyroid prescribed as an essential part of the treatment. We have not seen any reports regarding the results of this form of treatment recently, so it is possible that it has not been as successful as at first it promised to be, but there are many other possibilities in the way of food deficiencies that would be worth exploring. The skin is notoriously susceptible to food deficiencies even when the general nutrition of the body appears to be well maintained, and the tea-estate coolie, though he is assured of sufficient rice, is often unenterprising regarding the other items of his diet. This will apply particularly to the new coolie who is a stranger in the land and knows nothing of, and probably has little taste for, the various accessory food substances available locally that help to supply essential dietetic substances amongst people who seldom eat meat or drink milk. The age and sex distribution may, as we have suggested above, be explainable on other grounds, but it is known that there are slight variations in the nutritional requirements of the different age groups, and it is possible that there are differences in the dietetic habits. In Dr. Ghosh's series there is a striking difference between the age distribution in males and females; the difference may be dependent on chance, the numbers being small, or on the greater number of young girls employed amongst the tea, but there is a possibility that the earlier development of females in this country may in some way be an associated cause. To summarize, it cannot be claimed that the case in favour of a nutritional basis to predisposition to Naga sore is as yet a strong one, but it is an aspect of the problem that has hitherto been neglected. Before the case can be judged more epidemiological facts and figures, which can only be supplied by the man actually working in the areas where these sores occur, are necessary; that is to say, it is field rather than laboratory work that is at present most urgently required.

Dr. Ghosh has suggested that the ulcer is normally self-limiting and that if it is left alone it will eventually heal; this is not the general opinion of writers on this subject. A point in favour of this suggestion is the considerable degree of uniformity in size and shape that the ulcers usually present; the large serpiginous type, involving half the circumference of the leg, is however not infrequently encountered. It would probably be worth investigating whether the unchecked extension in these cases is due to some secondary aetiological factor, such as syphilis. It is not a point of great practical importance whether the ulcers, untreated, will eventually heal or not, as in any case the process would be a protracted one; rapid healing is to the advantage of all concerned and is always the main objective of those who have to treat them.

There is almost complete uniformity of opinion regarding the first stages of treatment; here practice agrees with the principles of treatment that are based on our knowledge of the pathology of the disease. Before any improvement can be expected to take place the slough and necrotic tissue must be removed; some form of vigorous treatment is indicated, either surgical scraping or frequent hot fomentations, followed by thorough cauterization of the base by pure carbolic acid, strong copper sulphate (25 per cent) and carbolic acid solution, or powdered potassium permanganate, the last-named being very painful and for that reason not to be recommended where popularity of the treatment is aimed at. The fusiform bacillus is an anaerobe and therefore does not flourish under these conditions; once the ulcer can be made to present a healthy granulating surface healing will commence and usually proceed uninterruptedly. Should however the slough re-form, it must again be removed.

Over the next stage of the treatment there seems to be a variety of individual opinions; some recommend the frequent application of the caustic lotion, others daily or twice-daily bathing with milder antiseptic lotions followed by wet dressing, dry dressing with cyanide gauze, dusting with an antiseptic powder, or the application of an antiseptic ointment. Iodoform seems to be popular both as a powder and as an ointment; a powder containing one part of iodoform and three of subgallate of bismuth is used at the Calcutta School of Tropical Medicine, and gives good results.

From Africa comes the suggestion that a modified form of the Winnet-Orr treatment for osteomyelitis should be used; one can see great administrative advantages in adopting this method, but it is essential that the ulcer should first be brought to the healthy granulating stage, otherwise it would seem that the procedure were playing into the hands of an anaerobic organism. A paste containing zinc oxide (1 part), and iodoform (2 parts) in liquid paraffin, made up to the consistency of clotted cream, is

applied freely to the granulating ulcer, over this is placed gauze and cotton-wool, and finally a plaster of Paris bandage is applied to the whole circumference of the limb extending several inches above and below the ulcer. As an alternative to the plaster of Paris, the limb can be bound round with adhesive surgical plaster, but this would certainly be more expensive. The ulcer remains 'locked up' in this dressing for at least a week. If this procedure is successful—and in Africa it is claimed that it is—it possesses many obvious advantages, amongst which are that the patient cannot interfere with the dressings and that the treatment is ambulatory.

Without any exact knowledge regarding the mode of spread of the disease, it is not possible to suggest specific preventive measures, but, on the assumption that there is an essential primary lesion on to which is implanted a secondary anaerobic infection that probably comes from the soil, certain preventive measures have been adopted on tea estates. One of the most popular of these is to make the coolies, on their way back from work, walk through a tank containing some antiseptic lotion. This seems a rational procedure, but we have never seen any strong evidence adduced in its favour; weak antiseptic solutions are liable to be a snare, and it seems just possible that if the antiseptic solutions were not strong enough, a common tank, through which hundreds of coolies walk daily, might soon become a rich culture of septic and other organisms, and at the other end of the scale if the antiseptic solutions were too strong it might give rise to dermatitis in the specially susceptible. There seems to be room for further statistical and bacteriological investigation of this method of prevention. On the other hand, individual washing of the feet with weak antiseptic solution or even with plain water could only do good, but in a tea-estate labour force it would be practically impossible to enforce this procedure.

The wearing of puttees is again a rational measure, if trauma is the main predisposing cause, but if 'dermatitis' is the commoner precursor, as Roy's figures suggest, then damp puttees would probably not help matters. We believe that this measure has been tried, but we have seen no reports regarding its success or failure.

Another method, one that Dr. Ghosh suggests, is the frequent careful inspection of the legs of coolies and the early treatment of any cuts or other skin lesions on the legs with iodine, mercury ointment, or whatever the special condition indicates. This measure to be successful will demand the personal attendance of the assistant medical officer at 'leaf-weighing', but in estates where this condition is a serious problem each year it might be worth adopting, even if it meant employing temporarily an additional assistant medical officer.

THE SIGNIFICANCE OF THE THYRO-THYMIC LYMPH SYSTEM

By M. M. CRUICKSHANK, B.Sc., M.D., Ch.M.
MAJOR, I.M.S.

District Medical Officer, Madurai

THE thyro-thymic lymph system, what is its significance; does the presence of such a system help us to a better understanding of thyroid conditions; does it in any way help us to correlate the histopathological with the clinical condition in cases of thyroid dysfunction?

To appreciate better the significance of the thyro-thymic lymph system, attention must be drawn to certain facts with regard to the structure of both thymus and thyroid.

The discovery of the thyro-thymic lymphatic channels is not of recent date, but was the result of work done by Sir Astly Cooper, who described them in 1832. Recently, Sir Arthur Keith has found in the museum of the Royal College of Surgeons, England, injection specimens of thyroid and thymus attributed to Sir Astly Cooper.

In a 'Physiological essay on the thymus gland' Simon in 1845 demonstrated that in birds and mammals the thymus was a neck organ, the bulk of the organ indeed being not mediastinal, but lying anywhere in the region above or below the thyroid. Simon pointed out that structurally the thymus consisted of plicated, sacculated tubes lined with endothelium, the saecules containing aggregations of lymphocytes.

The lymph channels, the essential structural feature of thymus, persist throughout life. It is the function of the thymus which changes, and this only quantitatively, because it can be shown that the lymphocytic function may persist to some degree throughout life.

These lymph tubes of the thymus are the blind terminals of the special thyroid lymphatics, and the reservoir for the storage of the special lymphogenic secretion of the thyroid. Thus the thyroid and thymus are but different parts of the same organ, as Sir Astly Cooper's injection specimens would show.

In Graves' disease there is a great increase of the lymphoid tissue of the thymus, which is shared in by those aggregations of epithelial cells, known as Hassal's corpuscles, the finding of which in sections is taken as evidence of thymic tissue. This dual increase is also observed when an animal is fed on thyroid.

Let us turn now from the extra-thyroidal portion to the intra-thyroidal portion of the thyro-thymic lymph system to the thyroid gland itself; lymph spaces within the thyroid were described by Boechat in 1873 and by several investigators since that date. The thyroid consists of groups of follicles, each follicle consisting of

columns of thyroid epithelium lying in a lymph space, bathed with lymph. Groups of such follicles, separated by perifollicular and inter-follicular lymph spaces, are enclosed within a fibro-elastic capsule lined with endothelium. Such a group is known as a lymph sinusoid or gland unit, and groups of gland units, clustering round a central intralobular lymphatic, constitute a lobule of the thyroid gland. These central intralobular lymphatics, draining lymph from the sinusoids, unite as interstitial lymph channels and run in the interstitial tissue of the gland with the branches of the main artery of the thyroid, the inferior thyroid.

These lymphatics emerge as discrete trunks at a well-marked hilum on the postero-mesial aspect of the gland, where the artery enters. It is important to note that these *special lymphatics* do not follow the veins, but run with the arteries. The ordinary lymphatics of the thyroid accompany and emerge with the veins, which are spread all over the capsule of the gland. These are the *lymphæ comites* and drain into the deep cervical glands.

The special lymphatics can be traced up and down the neck as discrete vessels and end in thymic tissue, whether that tissue be in the mediastinum, in the region of the thyroid itself, or on the lateral aspect of the neck in the region of the mastoid process.

We must note therefore that the thyroid gland has two sets of lymphatics—(1) special or specific lymphatics, which course with the arteries and drain into the lymph channels of the thymus, and (2) *lymphæ comites*, the ordinary lymphatics, which emerge with the veins and drain, as do lymphatics from other organs, into lymph nodes, in this case into the deep cervical lymph glands.

The proof that the lymphoid nodes into which the special lymphatics drain are thymus depends on the presence of Hassal's corpuscles in the tissue. Pathological material also provides proof of the course taken by these special lymphatics; in malignant disease the growth can sometimes be traced from the thyroid sinusoids along the lymphatics to the thymic nodes.

In lymphadenoid goitre in man, and in the similar condition produced experimentally in rats by Sir Robert McCarrison, the whole of the thyro-thymic lymph system can be demonstrated to be filled with lymph and proliferating endothelium. Further Williamson and Pearse, from a study of comparative anatomy and embryology, infer that the thyro-thymic lymph system of mammals is derived from a thyroid gill lymph system found in fish.

In man the gills have disappeared, but the original lymph space remains as the thyro-thymic lymph system, to fulfil some function which was once included in the general respiratory function in fish.

Perhaps herein lies a clue to the function of the thyroid apparatus as a whole in man.

Does this fact of a thyro-thymic system, filled with lymph, lymphocytes and proliferating endothelium, throw any new light on the physiology of the thyroid?

Histologists have maintained that some secretion of the thyroid actually leaves the gland by the lymphatics. Thyroid activity being bound up in the mind of the physiologist with iodine and iodo-colloid (thyroxin) alone, no proof of the histologists' statement was forthcoming.

This secretion, which leaves the thyroid by the special lymphatics, contains no iodine nor is iodine or thyroxin found in the thymus. It has nothing to do with iodo-colloid, with that peculiar intermingling of function where iodine is brought to the thyroid in the blood, colloid is stored in the vesicles, and thyroxin is discharged from the gland by the blood stream.

What then is this secretion of the thyroid?

Williamson and Pearce have shown that 'this secretion is the misnamed secretion of hyperplasia, with which physiologist, pathologist and surgeon alike are so familiar. This secretion is not only histologically different from iodo-colloid, but neither is its chemical nor is its biological action that of iodo-colloid. The two secretions are in fact distinct entities: they are neither similar nor derivative. This other secretion can be seen traversing the epithelium from the lumen of the follicle to enter the pericellular lymph spaces, and, as we have already seen, can be followed from thence into the thymus. On reaching thymic tissue it stimulates the endothelium of the lymph spaces to produce lymphocytes. Under certain normal conditions this secretion may even stimulate the endothelium of the thyroid lymph sinusoids or the interstitial lymph channels of the thyroid to emulate the thymus producing thereby a characteristic aggregation of lymphocytes in the thyroid. In other words this secretion can stimulate the production of lymphocytes throughout the thyro-thymic lymph tract. The secretion is in fact a lymphogenic substance which iodo-colloid (thyroxin) is not'.

Experimental work shows that the implantation into the peritoneal cavity of dogs, of thymus from cases of Graves' disease produces the full syndrome of the disease.

Williamson and Pearce point out that this thyrotoxicosis is due to the failure of the lymphocytic endothelium of the thymus to effect the natural detoxication of the normally toxic lymphogenic secretion of the thyroid, which is normally stored in the thymus.

Thyroid then possesses two lymphatic systems and produces two secretions, one the iodo-colloid, the other the lymphogenic.

Do these facts with regard to the physiology of the thyroid help us towards a better terminology in our classification of the varieties of goitre?

Dunhill very correctly says 'I cannot agree that the clinical condition of the patient should

be ignored and only the histopathological appearances used in the grouping of goitres'.

I feel that clinicians will appreciate the classification of Williamson and Pearce, the names giving clear pictures of the possible combinations of the functions of the two secretions of the thyroid.

A study also of various classifications shows clearly how the various histopathological findings overlap and how the varied clinical conditions intermingle.

From a classification based on histopathology one passes to one based on a consideration of stimuli normal and abnormal on a gland which may be normal, subefficient, or diseased, and finally to a classification that pictures the possible combinations of two functions, colloid function and lymphogenic function.

If we attempt to answer Boyd's question 'Is this hyperplasia the cause of the hyperthyroidism?', we open up the big question of the relation of thyroid to Graves' disease. If the hyperplasia is the thyroid's response to the demands of the body for some additional secretion, then removal of the large parts of a struggling gland is hardly the way to help out the demand. If however the pure hyperplasia of Graves' disease results in the overproduction of a toxic secretion with which thymic endothelium is unable to deal, then it is reasonable to remove, in part at least, the seat of manufacture of the toxin—the thyroid gland.

Among the lymphatic conditions of surgical interest, which an appreciation of the thyro-thymic lymph system may help to explain, are the cystic hygromas. These swellings are endothelial-lined cysts; they occur in positions where thymic tissue is to be found, and they tend to manifest themselves or enlarge at those times when the lymphogenic activity of the thyroid is enhanced, namely just after birth and again about puberty.

Are cystic hygromas then due to developmental abnormalities in the thyro-thymic lymph tract? Of perhaps more serious interest is the relation of thyroid lymphatics to thyroid neoplasms, and the vexed question of their resulting metastases, the confusion centring around these being evidenced by the series of anomalous names used to describe thyroid tumours.

Every surgeon is aware of the frequency with which some thyroid cancers invade the mediastinum without invading the deep cervical glands and how these cancers may be found anywhere in the neck from the mediastinum to the base of the skull, and how on the other hand some cancers invade the cervical lymph glands.

It is held that for the three classes of thyroid carcinoma, (1) scirrhus or carcinoma simplex, (2) papilliferous adenocarcinoma, and (3) malignant adenoma, the first two disseminate to lymph nodes, while the third, the malignant adenoma, does not do so, so long as it is contained within its capsule, but that, even while the primary growth is small and the capsule still intact,

CLASSIFICATIONS OF THE VARIETIES OF GOITRE

AUTHOR.

DIFFUSE GOITRE WITH INVOLUTION.

(including)

E endemic or simple

Goitre of adolescence

The vague Colloid goitre

Hyperplasia - compensatory

Involution

Hyperinvolution - [with development of colloid goitre]

Stroma changes - [with formation of nodules]

colloid or foetal

The adenoma - a mere incident in the

course of the pathological process, has nothing to do with the thyrotoxicosis which may develop.

These are not true adenomata but rather involu-

PHYSIOLOGICAL ENLARGEMENT.

(including)

Adolescent goitre

Hyperplasia -

Involution

Hyperinvolution

Stroma changes and fibrosis

physiological

normal

Stimulus

Gland

(1) Diffuse involutional goitre, with sooner or later nodular changes and

(2) Nodular involutional goitre (non-toxic adenoma)

1. Single - colloid adenoma - cystic adenoma,

2. Multiple - 'pudding' goitre (de Quervain).

physiological, if excessive.

normal or sub-efficient.

COLLOID HYPERTROPHY

Function - normal

Iodo-colloid secretion and storage - normal

Lymphogenic secretion - normal

Function - Iodo-colloid storage predominating.

Lymphogenic secretion in abeyance.

STROMA PARENCHYMATOSA ET COLLOIDES.

CONTINENTAL WORKERS.

A classification which shows that continental workers realized earlier than did English investigators that the varieties of goitre depended on a combination of the functions of the thyroid secretions.

MODULAR GOITRE.

DIFFUSE GOITRE WITH HYPERPLASIA.

Cause unknown - commonly held to be due to over production of the internal secretion of the thyroid.

Diffuse hyperplasia - not compensatory

Development of adenomata - involution

Definite collections of lymphocytes in the stroma.

Is this hyperplasia the cause of the hyperthyroidism?

The hyperplasia may disappear and the gland revert to a colloid condition and still the symptoms of hyperthyroidism persist.

Histopathology

TOXIC GOITRE

(1) Primary (Graves) diffuse hyperplasia - not compensatory.

(2) Secondary

Stimulus - abnormal, accompanied by alteration in secretion.

Gland - normal - sub-efficient or diseased, with resulting thyrotoxicosis, the degree depending on the condition of the gland. If a normal gland then profound: if a diseased gland less profound depending upon the amount and quality of active thyroid tissue left to react.

LYMPHOGENIC HYPERTROPHY.

Function. Iodo-colloid storage in abeyance.

Lymphogenic secretion predominating, not being toxicated.

STROMA PARENCHYMATOSA DIFFUSA.

dissemination may occur by invasion of blood vessels. Why this atypical distribution? Simply because there are two distinct sets of thyroid lymphatics.

The carcinoma simplex and the papilliferous carcinoma invade lymph nodes *via* the lymphæ comites, the ordinary capsular lymphatics. The malignant adenoma invades the special lymphatics, the thyro-thymic lymph system, and remains within it until blood vessels are invaded. There we have a broad classification of thyroid tumours: (1) those which invade the ordinary capsular lymphatics, and (2) those which invade the thyro-thymic lymph system.

Again, why these anomalous names for thyroid tumours—e.g., aberrant thyroid tumour, metastasizing adenoma, benign metastatic, benign recurrent adenoma, and benign metastasizing goitre.

Why? Because it was not realized that the thymus, including the nodes of thymic tissue in the neck, and thyroid were functionally one apparatus, and that a growth, confined within the thyro-thymic lymph system, was still a growth confined within the organ of its origin.

For instance an aberrant thyroid tumour is explained, so I take it, as a secondary growth occurring in a near or distant thymic lymph node, that is, still within the thyro-thymic lymph system. Those who hold this idea are of course fully aware of the theories of origin of lateral aberrant thyroids, from isolated branchiogenetic rests, from the ultimo-branchial body, a remnant of the fifth pharyngeal pouch and so on. The origin of the lateral aberrant thyroids cannot be discussed here. A metastasizing adenoma is similarly explained as the spread of the adenoma within the confines of the thyro-thymic lymph system.

When these tumours invade vessels and metastases occur in bones then further confusion arises, because certain of these metastases have been found functionally active and to consist of normal thyroid tissue, or what appears to be normal thyroid tissue.

The classical case is that of von Eiselsberg, in which tetany (? cachexia strumipriva), following removal of a carcinomatous thyroid, was relieved when a secondary appeared in the sternum and reappeared when the sternal growth was excised.

Can a malignant thyroid produce a benign metastasis?

Can a benign thyroid produce a benign or malignant metastasis? I should think the answer is 'no' in both cases. Then why should such questions even arise and what is the reason for such a term as benign metastasizing goitre?

Return to the tumour confined within the organ of its origin. No invasion of lymph glands occur, but, even while the tumour in the thyroid is so small as to be overlooked, so that the gland is considered normal or so small as to be looked upon as a small benign adenoma, even

at that stage invasion of vessels may have occurred. Tissue emboli then are responsible for the production of secondaries and tissue emboli can reproduce *in toto* the form of the organ of their origin and furthermore such secondaries can show functional activity.

A normal thyroid, a colloid thyroid, a thyroid containing a small adenoma, or a thyroid containing a malignant adenoma, each has at some time been reported as having produced a metastasis consisting of normal thyroid tissue.

That a carcinomatous thyroid appears to produce a metastasis that has the appearance of normal thyroid tissue is recognized and explained by the French term of 'the return towards the normal'. The term 'the return towards the normal' simply describes what appears to be normal, but in reality neither the thyroid nor the metastasis are normal. These metastases, the result of tissue emboli implants, give a very different picture from the multiplying cellular seeds of a true carcinoma, which can never show functional activity, but that they are malignant and the product of a malignant tumour must be accepted.

This because 'the epithelial appearance of different benign adenomas, or different parts of the same adenoma, may vary so widely, and because malignant change may take place with so little alteration in the characters and arrangement of the epithelium. Neither the character of the cells, nor the mitoses, nor the structure of the vesicles admit of any definite conclusion as regards non-malignancy or malignancy. From a pathological standpoint the dividing line between benign and non-malignant tumours can probably be nowhere drawn with greater difficulty than just here'. These facts, together with the fact that secondary deposits retain the characters of the primary tumour and that both may retain specific glandular structures, explain why it was thought that a malignant tumour might give rise to a metastasis consisting of normal thyroid tissue.

Malignant adenomata make up 85 to 90 per cent of thyroid cancers and it would appear to be a matter of great difficulty, at least in some cases, for even an expert pathologist to decide whether a thyroid adenoma and its metastases are malignant or not. Little wonder then, that investigators had recourse to such anomalous names to describe what they found in such puzzling atypical cases.

We saw in dealing with thyroid dysfunction that we may be dealing with a stimulus which may be normal or abnormal, affecting a gland which may be normal, sub-efficient, or diseased.

Similarly, Dunhill suggests that it may be held that neoplasms of the thyroid are the result of a stimulus, which may be normal affecting a gland which is sub-efficient or diseased or the result of a stimulus so excessive as to be abnormal and amount to irritation.

MATERNITY- AND CHILD-WELFARE TRAINING

By J. M. ORKNEY, M.B., CH.B., D.P.H., W.M.S.

(From the All-India Institute of Hygiene and Public Health, Calcutta)

A MATERNAL mortality of 200,000 per annum, stillbirths numbering 340,000 and the enormous sum of 2,859,797 deaths amongst children under five years of age—that is, 43 per cent of the total deaths registered yearly in India—is evidence enough, without elaboration, that the time has come for India to set herself seriously to a consideration of the problems raised by this excessive wastage of life and to the evolution of some progressive policy with regard to maternal welfare and child care. Deaths are only one aspect and perhaps not the major aspect of the problem. Cholera over the last few years has accounted for a yearly average of 225,187 deaths, a problem of similar magnitude so far as deaths are concerned, though occurring in a liable population four times as large, but cholera does not leave behind a disablement rate of 30–35 per cent, nor is its effect on the future generation comparable with the ravages caused in the family by the death or ill-health of the mother. The cholera problem is being tackled, but very little has yet been done for the protection of mothers and children.

The influence of the less tangible evils, instability of temperament and character, arising from maternal ignorance, mismanagement and neglect cannot be accurately assessed but there is abundant evidence of their importance in the history and international standing of the race, and no nation which values its good name and place amongst the world powers can longer neglect measures for the education of its mothers and the well-being of its children, the future directors of its destiny.

The child-welfare movement offers the most hopeful method of tackling the problem of reducing deaths and promoting health. It has proved its value over and over again in western countries and from small beginnings has extended its influence to include ante-natal care, the midwifery services, infant and child welfare proper and the nursery school. It has forged close links with the school medical service, and the executive officers, the doctor and the health visitor are not infrequently common to both services. The starting point of the movement is not important; the midwife may be first on the field, the health visitor, or the administrator. So long as the foundations are well and truly laid extension is possible in any direction. Up to the present India has been able to call to her aid the midwife and the health visitor, but the past history of the maternity- and child-welfare movement in India proves abundantly that something more is needed. It is widely recognized that no degree of excellence of administration can overcome the handicap imposed by

lack of skill and knowledge in the actual worker, but the converse, which is equally true, seems somehow to have escaped notice in this part of public health, and the services of skilled midwife and health visitor have often been rendered ineffective by misdirection, sometimes by the unenlightened enthusiasm of the philanthropist and often by the insatiability of the official body for figures and yet more figures. For instances of misdirection we have not far to look; in a large town in India there were 25 municipal midwives; in 1931 these women conducted 7,132 deliveries and attended 141 other cases who ultimately were delivered in hospital—a total of 7,273 cases. Each midwife therefore conducted 291 cases during the year. After allowance has been made for one weekly day off-duty and the yearly holiday of one month this works out at just over one delivery per day per midwife. Puerperal visits are paid for 10 days and the midwife will therefore in addition to one delivery visit 9 lying-in women. She is further required to pay 25 house-to-house visits daily to get in touch with the expectant mother. Confinements vary in duration and an average of 4 hours' attendance on any case is a very minimum estimate. Visits during the puerperium are for the purpose of attending to the local and general cleanliness and comfort of the mother, the establishment and management of breast feeding, the care and cleanliness of the baby and the general hygiene of the surroundings; no one can accomplish these duties satisfactorily in less than 30 minutes. Nine puerperal visits therefore means another 4½ hours duty daily. House-to-house visiting is an uneconomical way of doing ante-natal work. It wastes the midwife's time, gives a feeling of false security and is useless from a preventive viewpoint. Even if the midwife allows only 2 minutes per house she brings her total working day up to 9½ hours irrespective of time spent in travelling and in writing up her records. The times allowed have been reduced much below the ideal and even below the safe limit and yet the working day of the midwife is, on the face of it, almost a physical impossibility. It is made to function by the delegation of work which properly lies within the province of the midwife to the indigenous *dai* or the relatives, and so defeats the object of the service which is to make confinement safe and to raise the standard of health. Other examples of defective planning can be found in the distribution of milk at the milk kitchens, where breast feeding is discouraged by supplying milk to newborn infants, instead of to the nursing mother, and by bringing the supply to an end at the age of two years before the child is even firmly established on the ordinary defective adult dietary, or in the infant-welfare service, where the visits are discontinued when the child is three months old, just at the age when the results of maternal mismanagement and unhygienic habits are becoming manifest.

Enough has been said to illustrate the point that a special training is required for the medical officer in charge of maternity- and child-welfare schemes. Western countries have recognized this; the Society of Apothecaries instituted the degree of Master of Midwifery (M. M. S. A.) a few years ago and in March of this year the Society of Obstetricians and Gynaecologists decided to confer a diploma (D. O. O. G.) to post-graduates with special training in midwifery and gynaecology. The diploma in maternity and child welfare (D. M. C. W.) given by the Faculty of Tropical Medicine, Bengal, is on similar lines, but as will be seen from the brief outline given below it is more comprehensive and ensures a sound training on preventive medicine and public health practice.

The course for the diploma in maternity and child welfare at the All-India Institute of Hygiene is designed to meet one of the outstanding needs of India to-day, namely, for a trained body of medical women to reorganize existing welfare schemes, to formulate schemes suitable for rural as well as urban India, to organize and administer the work in larger districts and provinces, and to make the schemes effective by personal participation in the executive duties of the maternity- and child-welfare officer. The last qualification is by no means the least important. No one can successfully plan and organize who has not a thorough and lasting knowledge of the subject: this is gained only by practical personal experience of the duties and difficulties of the executive officer.

The aim of the course for the diploma in maternity and child welfare is therefore to give the student a thoroughly practical training in the administrative and clinical aspects of maternity and child welfare and school hygiene, and to make her sufficiently conversant with public health in general to fit into the complete scheme this fundamental and integral part.

The present training of the medical student in obstetrics is admittedly unsatisfactory; opportunities for the study of children's diseases and for the treatment of venereal diseases are very limited in most Indian Universities to-day and for these reasons post-graduate training in these subjects is included in the curriculum. The possession of the D. M. C. W. will be a valuable guide to local authorities in choosing a medical officer for their midwifery services because in selecting candidates for the diploma attention is paid to previous experiences in midwifery and diseases of children and on this foundation is superimposed an intensive post-graduate course in up-to-date methods.

Skill, experience, and judgment in midwifery and in the treatment of disease is however only half the equipment of the well-trained medical officer. Her outlook must be preventive. Preventive medicine is invading the medical curriculum, but still the bias of the graduate is towards the diagnosis and cure of disease; she is prepared to advise on ill-health, but rarely

to aid the mother of the healthy child to prevent disease or to guide her to make the most of the physical and mental endowments of her children; she can minister to the body but knows little of the 'motives and mechanisms' of the child's mind and rarely recognizes the environmental factors underlying anti-social behaviour or the psychological significance of widely different physical symptoms; she may or may not advocate conception control, but she is ill prepared to arouse in the parents a sense of responsibility for the nature and number of their offspring. In short the average doctor recognizes only disease, not degrees of health, she substitutes the easier 'bottle' for explanation and education, and leaves the general level of physical and mental health very much where it was before she began her ministrations. The diploma course is designed to correct this bias; it includes lectures on child development and management, child psychology, genetics, and school hygiene, and the welfare unit attached to the All-India Institute of Hygiene provides ample facilities in home, school and clinic for the practical application of theoretical knowledge. This part of the training is invaluable since from personal experience and practice alone come wisdom and understanding to the doctor, and lasting benefit to the community.

The further training for the diploma in maternity and child welfare lies along lines similar to those for the diploma in public health and classes in vital statistics and epidemiology, sanitary law and public health administration and general hygiene are held jointly for the two diplomas. For the former, however, emphasis is placed on the methods of surveying an area with regard to its need for midwives, maternity homes and hospitals, infant and child welfare, and school medical services, and on the organization and administration of effective schemes for maternal and child life protection.

The maternity and child-welfare movement has timed its birth in India under very unfavourable conditions, but there is little doubt that it has come to stay. There are already signs that the present period of quiescence will shortly be followed by a period of active growth. Enlightened authorities are even now asking themselves whether they are getting value for the money spent on treating established disease, or whether the time has not come for them to reorganize their schemes and to introduce a more positive policy towards health. The whole superstructure of public health is built on the foundations laid at and around birth, and in the interests of efficiency, economy and the well-being of the nation a sound maternity- and child-welfare service is vitally necessary. They labour in vain who labour to produce an A-1 nation if the basis, soundness of body, stability of character and alertness and vigour of mind, has not been well and truly laid in infancy and youth. The questioning of

to-day is the forerunner of the demand of tomorrow and the object of the diploma course in maternity and child welfare is to meet this demand for a body of trained medical women

fitted to take up executive or administrative posts in any scheme for safeguarding the mother's life and for conserving the child's birthright of health.

Medical News

FRANCE HONOURS BRITISH RESEARCH

THE President of the French Republic has paid a notable tribute to English medical and chemical research by conferring the honour of La Croix de Chevalier de la Légion d'Honneur upon Sir Henry Wellcome, LL.D., F.R.S., the Founder of The Wellcome Research Institution and its associated research laboratories and museums, in which are included The Bureau of Scientific Research, Physiological, Chemical and Entomological Research Laboratories, and The Museum of Medical Science and The Historical Medical Museum.

These research laboratories and museums, associated together in The Wellcome Research Institution, whose magnificent new building in the Euston Road, London, occupies a site having a frontage of 360 feet, have, by their original medical, chemical, physiological and historical researches contributed largely to international scientific knowledge, a fact which finds recognition in the honour bestowed upon the Founder by the Government of France.

BOMBAY MEDICAL COUNCIL

THE following extract from the summary of the proceedings of the meeting of the Bombay Medical Council held on the 5th February, 1934, is published for information:

The Council resumed consideration of the adjourned inquiry in the case of Mr. Motiram T. Ramchandani, M.B., B.S. (Bom.), of Station Road, Lucknow, in which he was charged as follows:—

That on or about the 9th May, 1932, without having previously had one Chahitey Lal under his treatment or observation, he gave him or some person on his behalf a certificate to the effect that the said Chahitey Lal was under his treatment from 29th February, 1932, to 3rd March, 1932, for malarial fever, which certificate was false to his knowledge and that he gave such certificate for the purpose of making it possible for the said Chahitey Lal to take up the plea of *alibi* in a murder case in which the said Chahitey Lal was one of the accused and that in relation thereto he had been guilty of infamous conduct in a professional respect.

The Council held that Mr. Ramchandani had been guilty of infamous conduct in a professional respect and was directed to remove Mr. Ramchandani from the Bombay Medical Register.

The Council resumed consideration of the adjourned inquiry in the case of Mr. N. K. Panse, L.C.R.S., of Kasba, Sholapur, in which he was charged as follows:—

That on or about the 13th April, 1932, he gave to one Mrs. Rukhminibai Balramdas Pujari or some person on her behalf a certificate to the effect that the said Mrs. Rukhminibai Balramdas Pujari was under his treatment from 3rd March, 1932, to 24th March, 1932, for neuritis of the ulnar nerve and that she was not in a position to attend to her duties as the pain was severe, which certificate was false to his knowledge and that he gave such certificate for the purpose of making it possible for the said Mrs. Rukhminibai Balramdas Pujari to prefer an appeal to the Assistant Sessions Judge, Sholapur, in connection with a suit which was dismissed for default by the Joint Sub-Judge, Sholapur, and that in relation thereto he had been guilty of infamous conduct in a professional respect.

The Council held that Mr. Panse had been guilty of infamous conduct in a professional respect and the Registrar was directed to remove Mr. Panse's name from the Bombay Medical Register.

The Council considered a motion made by a member that the meetings of the Council be thrown open to all who may apply to be present, excepting deliberations in penal cases, and it was resolved that registered medical practitioners up to a maximum of five may be allowed to be present provided that they state their reasons in writing to the Registrar why they wish to do so and obtain from him a ticket of admission.

The Council considered the case of Mr. S. P. Lulla, M.B., B.S. (Bom.), of Rampart Row, Karachi City, who had been summoned to appear before the Council to answer the following charges:—

(a) That he granted two vaccination certificates on or about 10th March, 1933, (1) one to Amir Mohamad and his wife Mst. Jawahar and (2) the other to Ali Asghar, Mst. Meryam, Nusrullah and Mst. Fatima, to the effect that they had been inoculated against small-pox and that they were fit to leave the Port (Karachi), while none of them had actually been vaccinated by him and they were unable, when inspected by the Port Health Officer, Basrah, to show any signs or marks of having been vaccinated and had, therefore, to be vaccinated at the Port Health Office, Margil, Basrah;

(b) That later he also granted another certificate, dated 17th March, 1933, to one Mr. Jacob Davidoff to the effect that he had been inoculated against pox and that he was fit to leave the Port but he had subsequently to be vaccinated by the Surgeon of S.S. 'Vasna' with fresh calf-lymph on 23rd March, 1933;

(c) That the certificates in question were, therefore, untrue, misleading or improper and that in relation thereto he was guilty of infamous conduct in a professional respect.

The Council held that Mr. Lulla had been guilty of infamous conduct in a professional respect and the Registrar was directed to remove Mr. Lulla's name from the Bombay Medical Register.

The Council considered a representation made by Mr. P. B. Dewasthale, M.B., B.S., of Igatpuri, that medical graduates when summoned to attend courts should be allowed II Class railway fare, and it was resolved that Government be addressed with a view to the High Court being moved to modify the rules so as to allow II Class fare to medical graduates for attending courts.

The Council next considered the application of Mr. B. H. Bhatt, M.B., B.S. (Bom.), of Nadiad, requesting that his name, which had been removed from the Bombay Medical Register under section 9 of the Bombay Medical Act, 1912, may be restored to the Register, and it was resolved that, before taking final decision in the matter, the opinion of the Advocate-General should be obtained as to the action which the Council can take in case it differs from the recommendation of the Executive Committee under rule 94 (vi) of the Rules of the Council.

The Council considered a reference from the Bombay Government forwarding an application from Mr. Heramba Nath Chatterji for permission to be registered under section 7 (3) of the Bombay Medical Act, 1912, and resolved that Government be informed that there is no proof that Mr. Chatterji was in practice in this

Presidency before the 25th day of June, 1912, and that he cannot, therefore, be granted permission to be registered under section 7 (3) of the Act.

The Council considered a motion made by a member of the Council for the amendment of the Code of Medical Ethics and it was resolved that the Code should be amended so as to require the avoidance by registered medical practitioners also of the following practices:—

Associating with foreign medical men who do not possess a medical qualification recognized for registration by the General Medical Council as an additional qualification.

Associating with medical agents of manufacturers whose sole object is to advertise products of particular manufacturers.

Publishing, or sanctioning the publication of, in lay papers, the subject or substance of lectures in the diagnosis or treatment of diseases to be delivered by them.

The Council considered a reference from the Bombay Government forwarding a representation from Mr. U. I. Bhatt, Sub-Assistant Surgeon, Municipal Dispensary, Seeghelatti, Shimoga (Mysore State), requesting reconsideration of his previous application for permission to be registered under section 7 (3) of the Bombay Medical Act, and it was resolved that Government should be informed that the Council adheres to the opinion previously expressed by it that the applicant was not practising in the Bombay Presidency prior to June 1912 but in South Kanara District, as stated by him in his original letter to Government, and that he cannot be given permission to be registered under section 7 (3) of the Act.

The following six members were elected to constitute the Executive Committee for the year 1934:—

Dr. D. A. D'Monte, M.D., Dr. G. V. Deshmukh, M.D., Mr. Mangaldas V. Melita, O.B.E., Dr. Rajabally V. Patel, M.D., Lieut.-Col. W. C. Spackman, I.M.S., Sir Nasarvanji Choksy, Kt., C.I.E.

AN ADDRESS, DELIVERED AT THE FOURTEENTH ANNUAL MEETING OF THE CENTRAL CO-OPERATIVE ANTIMALARIA SOCIETY HELD IN CALCUTTA IN FEBRUARY 1934, ON THE BIOLOGICAL CONTROL OF ANOPHELES IN BENGAL

By C. STRICKLAND, M.A., M.D.

*Professor of Entomology, Calcutta School of Tropical
Medicine*

It has been repeatedly shown that mosquito larvæ and, in fact, few aquatic insects of any sort can be found in the water of big rivers, which shows that certain elements in the terrain can be excluded from the scope of antimalarial work. Let me assume then that you have in any locality decided whence your trouble is coming.

Now for malaria prevention let me first lay it down as an axiom that it is better policy from the financial point of view to rely more upon measures that are of a permanent nature, if in the circumstances of the locality any are feasible, rather than upon those that are temporary, and the charges for which are constantly recurring. For instance let us suppose you can get the same results by draining a swamp at a cost of Rs. 1,000, as from spraying it with oil at a cost of the annual interest on Rs. 1,000; it would be better to adopt the former measure. Although this point of view dominates our everyday life, nevertheless the Far Eastern Association of Tropical Medicine considered it worth emphasizing and expressed it in a resolution at their Congress in Calcutta in 1927.

Now what measures of more permanent nature might be feasible to suit the conditions of Bengal?

Let us first see if Nature can assist us. I have often noticed that if people have any work to do they are

very glad to put it on to someone else's shoulders, particularly if no payment has to be made. So perhaps we can put some of our work on to Nature's broad shoulders and get out of paying for it. She is dumb and cannot complain; on the other hand if we oppose Nature we will assuredly have to spend a great deal of time and effort in combating her infinitely greater power and then we may perhaps fail. She is so immeasurably more powerful than puny Man that all your effort might be wasted if you try to oppose her. Let me give you an example; here is a stream bending and curving through a field. Here is a man and he cuts a channel through the field to straighten out the stream. He is opposing Nature and all his work will be wasted for the stream will flow through the longer course because it is obeying certain Laws of Nature. You see therefore that if you want to get Nature to do your work for you, you must study what she is doing. In Bengal that is extremely difficult; for instance what is Nature doing to the surface of the land, the formation of the delta, the changes in the courses of rivers and their depth, the formation of *bhils* and so on? And yet you must try to understand all about it if you do not want to imitate the man trying to cut a straight course for the streamlet.

The difficulty of the subject may be realized when you remember that all the eminent engineers who have written about it have had different points of view in their explanation of what is going on. Dr. Chatterjee's paper 'The Romance of the Rivers of the Gangetic Delta' is a fascinating account of the main features of the problem.

One thing that Nature is doing in Bengal, as it does all over the world, is nurturing the growth of jungle. Can that take any of our work off our shoulders? If you look for breeding places of anopheles that carry malaria you will probably find that they do not occur under jungle or dense shade.* It has been shown that there are some places in Bengal where jungle could perhaps be utilized for the control of mosquitoes. That it does exist in some places is evidence that it can exist anywhere and does not interfere with the struggle for existence of the ryot. Therefore, one measure that your workers can safely follow in the villages is to encourage the growth of jungle over all collections of water. The Forest Department of the Government that conserves the Bengal forests may likewise be asked by you to see that streams and other collections of water now under forest be not exposed by cutting down the forest over them.

If in this respect you oppose Nature, that is if you try to combat the growth of her jungle, not only would you have to pay for it, but in this case you would be actually making matters worse. Get Nature to work for you, imitate her, assist her, but do not oppose her.

Now another way in which we might get Nature to work for us for nothing is by the encouragement of the natural enemies of the mosquito. You know that in our world all living creatures are preying upon one another, mosquito larvæ eat algae, and fish eat mosquito larvæ, and big fish eat little fish, and so on.

I am becoming always more convinced that the distribution of mosquitoes depends more upon the distribution and prevalence of their natural enemies than upon physical conditions, whereas in the old days mosquito larvæ were described as 'pool-breeders', 'stream-breeders', and so on, as if the physical conditions of the water in which they bred were the most important factors. There are of course many creatures that prey upon mosquitoes both in their aquatic condition and in their adult state; water insects and fish

* That malaria-carrying anopheles do not usually live in jungle is not a new discovery in Assam as stated recently in the press. Though I preached it to the British Medical Association in Assam in 1923, it was made in the Malay States about 1915 and is referred to in an editorial article in the *Indian Journal of Medical Research*, 1916.

devour mosquito larvæ, and birds, bats and spiders the adults.

There is little doubt but that permanent collections of water like tanks are of less danger than temporary collections. Probably the reason is that in the latter mosquitoes lay their eggs and complete their development within a few days before their most dangerous natural enemies have had time to establish themselves and to breed freely enough to deal with them. Moreover temporary collections of water being, *ipso facto*, shallow, are unfavourable to bigger creatures like fish, and the very fact that permanent collections are not dangerous shows that it is the bigger of the natural enemies like fish that are of more importance in nature. Small natural enemies like blood-worms can indeed be established in shallow water as quickly as mosquito larvæ.

Now, with such little knowledge of this subject that we have got, what should you do? The principle to follow is to make things less favourable to mosquito larvæ and more favourable to their enemies. Water tidiness takes away protection from larvæ, and such measures as converting shallow places into deep ones, cutting away shelving edges to streams, tanks, etc., removing big fish periodically, make things more favourable to their enemies like little fish. Then what about putting fish in or cutting channels from rivers into tanks, etc. Don't waste your money on it. You know that Nature abhors a vacuum, and you can just as well expect a natural vacuum in an unclosed vessel as a natural breeding place for mosquitoes like a tank without fish. Darwin emphasized that where there is food for an animal there the animal will be found, and fish will be found naturally everywhere that they could survive if you put them there by hand. How do they get there? By the overflow of big streams or in the case of closed tanks by the spawn being transferred on the feet of wading birds. Therefore, again let Nature do your work for you and save your money and your strength, by not *putting* fish into such places by hand, but on the other hand by expending it on making the place more *suitable* for your fish.

It is right to mention here the question of overflow irrigation, because it appears that this measure acts by distributing all over the surface of the land vast numbers of the natural enemies of mosquitoes.

Such antimalarial measures as the utilization of jungle and of the natural enemies of the mosquitoes may be called biological methods because you utilize living processes.

You may also sometimes get Nature to do your work for you in a physical way. As I stated above, you can get Nature to distribute your fish over the surface of the land by the overflow of the rivers, and other physical methods, if feasible, are excellent. Drainage of swamps and wide expanses of water reduces the area available for mosquito-breeding and would make jungle-growing much less necessary; but in a flat country like Bengal drainage is very difficult. Filling up borrow-pits with earth is a perfect measure, because it abolishes water altogether. Another physical measure which I would like to mention is the filling up of *bhils* with silt as we have done in some Assam tea gardens. You have a *bhil* alongside a silt-laden stream at a higher level—you connect up the two and the silt-laden water enters the *bhil*, and the silt is deposited and levels up the *bhil*. It seems to me this measure might be used in Bengal.

The use of crude chemicals, as far as I know, is a challenge to Nature as well as being a constantly recurring charge, therefore for financial reasons not to be recommended. They are a challenge to Nature because they destroy the water creatures other than mosquito larvæ and oppose Nature's methods. Sometimes one cannot get on without them; for instance I am looking after a big oil field in Burma where for various reasons it is best to use oiling.

But whatever you do is going to be hard work. I see no royal road to the prevention of malaria in Bengal, not even overflow irrigation. This is not going to be easy, for you may be sure the zemindars would not have embanked their rivers if they were not going to be better off for it, and they therefore no more want 'overflow' now than they did in the past. Are you going to oppose Man who after all is an important element in Nature? Further even if there were no zemindari embankments you would still have the natural embankments thrown up by rivers. Are you going to oppose Nature by throwing them down? Leaving overflow irrigation aside for the moment, I would summarize by saying, first find out in each locality what species of anopheles is causing you trouble, secondly, find out its main sources (and this should be rather by a malaria survey than by a mosquito survey), and, thirdly, deal with it either by the use of jungle, first draining the land as far as possible or by a combination of water tidiness, and making the breeding places as suitable as possible in many ways for small fish, or by the use of physical methods only, like drainage; or silting may be considered.

The Serum Treatment of Lobar Pneumonia

A Report of the Therapeutic Trials Committee of the Medical Research Council

(Abstracted from the *Lancet*, 10th February, 1934, p. 290)

DURING the last three years the Medical Research Council have assisted an inquiry at different centres in Great Britain into the therapeutic value of specific sera for lobar pneumonia; following the great development of similar work in the United States. When the Council appointed a standing Therapeutic Trials Committee in 1931, the investigation was placed under the control of that committee, and following is the summary of the evidence obtained:—

(1) Concentrated antiserum for type I pneumococcus reduced the fatality in type I cases of lobar pneumonia in adults between the ages of 20 and 40; from the total figures of the present inquiry, however, the treatment appeared to have little, if any, effect on

the fatality in older patients (aged 40–60). The treatment seemed definitely to reduce the average duration of fever and illness in patients who recovered, and there was a suggestion that it also decreased the liability to empyema among survivors.

(2) Similar effects were seen when type II antiserum was used for cases of type II lobar pneumonia.
